ENCYCLOPEDIA OF MATERIALS TECHNICAL CERAMICS AND GLASSES

EDITOR IN CHIEF

Michael Pomeroy

Bernal Institute, University of Limerick, Limerick, Ireland

SECTION EDITORS

Francis Cambier

Belgian Ceramic Research Centre, Mons, Belgium

Carmen Galassi

*National Research Council of Italy, Institute of Science
and Technology for Ceramics Faenza, Italy*

Stuart Hampshire

Bernal Institute, University of Limerick, Limerick, Ireland

Anne Leriche

*Laboratoire des Matériaux Céramiques et Procédés Associés,
Université Polytechnique Hauts-de-France, Valenciennes, France*

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers may always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

VOLUME 1

Overview: Manufacture of Ceramics and Microstructural Developments in Ceramics <i>Francis Cambier and Anne Leriche</i>	1
Synthesis of Oxide and Non-Oxide Advanced Ceramics <i>Prashant N Kumta</i>	2
Synthesis of Ceramic Powders by Wet Chemical Routes <i>Paola Palmero</i>	27
Self-Propagating High-Temperature Synthesis <i>Jerzy Lis</i>	40
Hydrothermal Synthesis <i>Ender Suvaci and Emel Özel</i>	59
Ultrasonic Sprayed Aerosol for Ultrafine Ceramic Powder Synthesis <i>Sylvie Foucaud and Yann Leconte</i>	69
Calcination and Phase Transformations <i>Gary L Messing</i>	83
Preceramic Polymers as Precursors of Advanced Ceramics: The Polymer-Derived Ceramics (PDCs) Route <i>Yuji Iwamoto, Günter Motz, Emanuel Ionescu, and Samuel Bernard</i>	93
Organic Additives in Ceramic Processing <i>Anne Aimable and Thierry Chartier</i>	103
Powder Mixing and Grinding Processes for Ceramics <i>David Houivet and Jérôme Bernard</i>	112
Powder Granulation and Compaction <i>Michele Dondi</i>	136
Colloid Casting Processes: Slip Casting, Centrifugal Casting, and Gel Casting <i>Nur S Yüzbaşı and Thomas Graule</i>	146
Processing of Ceramics by Direct Coagulation Casting <i>Margarida Almeida and Joaquim M Vieira</i>	154
Extrusion <i>Stuart Blackburn and Marcin Szymiczek</i>	162

Ceramic Injection Molding <i>Moritz v Witzleben and Tassilo Moritz</i>	179
Tape Casting and Lamination <i>Eric R Twiname</i>	189
Freeze Casting <i>Dominique Hautcoeur</i>	195
Additive Manufacturing <i>Andrea Zocca, Giorgia Franchin, Paolo Colombo, and Jens Günster</i>	203
Green Machining of Ceramics <i>Fabrice Petit</i>	222
Screen Printing <i>Danjela Kuscer</i>	227
Sintering of Ceramics: An Overview <i>Anne Leriche, Francis Cambier, and Stuart Hampshire</i>	233
Solid-State Sintering <i>John E Blendell and Wolfgang Rheinheimer</i>	249
Liquid Phase Sintering: Fundamentals <i>Suk-Joong L Kang</i>	258
Viscous Sintering <i>George W Scherer</i>	265
Hot Pressing and Hot Isostatic Pressing <i>Mathias Herrmann and Jan Räthel</i>	270
Reaction Sintering <i>Carmen Baudin</i>	278
Flash Sintering and Other Rapid Sintering Techniques <i>David Salamon</i>	286
Spark Plasma Sintering <i>Umberto Anselmi-Tamburini</i>	294
Cold Sintering and Hydrothermal Sintering <i>Graziella Goglio, Arnaud Ndayishimiye, Catherine Elissalde, and Clive A Randall</i>	311
Microwave Sintering of Ceramics <i>Jean-Marc Chaix</i>	327
Porous Ceramics Processing <i>Manabu Fukushima, Akihiro Shimamura, Paolo Colombo, Hideki Hyuga, Tatsuki Ohji, and Yu-ichi Yoshizawa</i>	342
Porous Ceramics Including Fibrous Insulation, Structure and Properties of <i>M Fukushima, T Ohji, P Colombo, and Y-I Yoshizawa</i>	346
Control of the Microstructure in Ceramics <i>Anne Leriche, Stuart Hampshire, and Francis Cambier</i>	349
Templated Grain Growth of Textured Ceramics <i>Gary L Messing</i>	367
Functionally Graded Ceramics <i>Omer Van der Biest and Achim Neubrand</i>	374
Transparent Ceramics: Materials, Processing, Properties and Applications <i>Marc Rubat du Merac</i>	399

Geopolymers and Geopolymer-Derived Composites <i>Waltraud M Kriven</i>	424
Overview: Characterization and Modelling of Ceramics and Glasses <i>Michael Pomeroy and Stuart Hampshire</i>	439
Ceramic Genomics: Total Bond Order Density <i>Wai-Yim Ching</i>	441
Predictive Modeling of Ceramic Materials <i>Sarah Guerin, Syed AM Tofail, and Damien Thompson</i>	475
Molecular Dynamics Simulations of Glass Structure <i>Mattias Edén</i>	481
Computation of Phase Diagrams for Ceramics <i>Sara Serena, Angel Caballero, Antonio H de Aza, and Maria A Sainz</i>	498
Characterization of Ceramic Powders <i>Martin J Murtagh and Navin Venugopal</i>	517
Amorphous Materials: Vibrational Spectroscopy <i>PF McMillan</i>	530
MAS NMR Analysis of Ceramics and Glasses <i>Yajie Gao</i>	536
X-Ray Powder Diffraction <i>Scott T Misture</i>	549
Case Studies in the X-ray Diffraction of Ceramics <i>Maurice Gonon</i>	560
Introduction to Transmission Electron Microscopy; The Basics <i>Ann-Katrin Fetzter, Maximilian Trapp, Stefan Lauterbach, and Hans-Joachim Kleebe</i>	578
High Resolution Analytical Electron Microscopy of Ceramics and Glasses <i>Jennifer Cookman, Michele Conroy, and Ursel Bangert</i>	600
Introduction to Three Dimensional Electron Crystallography <i>Andrew Stewart and Ute Kolb</i>	618
Preparation of Ceramic, Glass-Ceramic and Glasses for Microstructural Examination <i>Michael J Pomeroy</i>	634
Scanning Electron Microscopy for Ceramics and Glasses <i>Michael J Pomeroy</i>	651
Fractography: Brittle Materials <i>John J Mecholsky, Jr.</i>	662
Thermal Analysis Techniques for Technical Ceramics and Glasses <i>Michael J Pomeroy</i>	676
High-Temperature Characterization of Glasses and Melts <i>Sohei Sukenaga and Hiroyuki Shibata</i>	689
Overview: Mechanical and Physical Properties and Property Testing of Ceramics and Glasses <i>Anne Leriche and Francis Cambier</i>	704
Elastic and Inelastic Behavior of Ceramics <i>Daniele Mari and Robert Schaller</i>	705
Indentation of Ceramics <i>Emilio Jiménez-Piqué</i>	718

Contact Damage Resistance and Tribological Behavior of Ceramic/Carbon Nanostructure Composites <i>Manuel Belmonte</i>	733
Methods of Determination of Young's Modulus and Tensile, Flexural and Compressive Strength <i>Sylvain Meille</i>	745
Fracture Toughness Measurement <i>Tanja Lube</i>	762
R-Curve Behavior of Ceramics <i>Marc J Anglada</i>	775
Subcritical Crack Growth: Basic Relations and Experimental Evaluation <i>Malika Saâdaoui</i>	797
Subcritical Crack Growth: Modeling of the v-K Curve in Different Environments <i>Raul Bermejo</i>	811
Ceramics: Transformation Toughening <i>DB Marshall and RHJ Hannink</i>	818
Mixed-Mode Fracture and Microstructural Aspects of Crack Propagation <i>Delia Gutiérrez-Campos and Yuk Ming X Hung-Hung</i>	823
R-Ratio and Microstructure Effects <i>Delia Gutiérrez-Campos, Eliana Pinto-González, and Elvira Saab-Llatas</i>	841
Thermal Properties of Ceramic Materials <i>David S Smith and Benoît Naït-Ali</i>	855
Thermal Shock Behavior of Ceramics: Fundamentals and Thermal Shock Resistance Parameters <i>Carmen Baudín</i>	867
Thermal Shock and Thermal Fatigue Behavior of Ceramics: Microstructural Effects <i>Gilbert Fantozzi and Malika Saâdaoui</i>	879
Creep Behavior of Ceramics <i>Gilbert Fantozzi and Arturo Dominguez-Rodriguez</i>	891
Nonoxide Ceramics, Creep and Creep Rupture of: Silicon Nitrides and Silicon Carbides <i>SM Wiederhorn</i>	908
Dislocations in Ceramic Materials <i>Jacques Rabier</i>	911
Corrosion of Ceramics in Aqueous Environments <i>Mathias Herrmann</i>	921
Corrosion and Degradation of Glass <i>Dagmar Galusková and Dušan Galusek</i>	932

LIST OF CONTRIBUTORS FOR VOLUME 1

Anne Aimable

Institute of Research for Ceramics, French National Center for Scientific Research, University of Limoges, Limoges, France

Margarida Almeida

CICECO-Aveiro Institute of Materials and Ceramic Engineering, Department of Materials and Ceramic Engineering, University of Aveiro, Aveiro, Portugal

Marc J. Anglada

Polytechnic University of Catalonia, Barcelona, Spain

Umberto Anselmi-Tamburini

University of Pavia, Pavia, Italy

Ursel Bangert

University of Limerick, Limerick, Ireland

Carmen Baudín

Instituto de Cerámica y Vidrio, CSIC, Madrid, Spain

Manuel Belmonte

Institute of Ceramics and Glass (ICV-CSIC), Madrid, Spain

Raul Bermejo

Department of Materials Science, University of Leoben, Leoben, Austria and The Pennsylvania State University, PA, United States

Jerôme Bernard

Normandy University, UNICAEN, LUSAC, Caen, France

Samuel Bernard

University of Limoges, French National Centre for Scientific Research, Institute of Research for Ceramics, Limoges, France

Stuart Blackburn

University of Birmingham, Birmingham, United Kingdom

John E. Blendell

Purdue University, West Lafayette, IN, United States

Angel Caballero

Institute of Ceramics and Glass-Spanish National Research Council (CSIC), Madrid, Spain

Francis Cambier

Belgian Ceramic Research Centre, Mons, Belgium

Jean-Marc Chaix

Université Grenoble Alpes, French National Centre for Scientific Research, SIMaP lab, Grenoble, France

Thierry Chartier

Institute of Research for Ceramics, French National Center for Scientific Research, University of Limoges, Limoges, France

Wai-Yim Ching

University of Missouri-Kansas City, Kansas City, United States

Paolo Colombo

University of Padua, Padua, Italy and The Pennsylvania State University, University Park, PA, United States

Michele Conroy

University of Limerick, Limerick, Ireland

Jennifer Cookman

University of Limerick, Limerick, Ireland

Antonio H. de Aza

Institute of Ceramics and Glass-Spanish National Research Council (CSIC), Madrid, Spain

Arturo Dominguez-Rodriguez

University of Sevilla, Sevilla, Spain

Michele Dondi

CNR-ISTEC, Institute of Science and Technology for Ceramics, Faenza, Italy

Mattias Edén

Stockholm University, Stockholm, Sweden

Catherine Elissalde

CNRS, University of Bordeaux, Bordeaux INP, Pessac, France

Gilbert Fantozzi

University of Lyon, National Institute of Applied Sciences of Lyon, Materials: Engineering and Science (MATEIS), French National Centre for Scientific Research, Villeurbanne, France

Ann-Katrin Fetzter

Technical University of Darmstadt, Darmstadt, Germany

Sylvie Foucaud

University of Limoges, Limoges, France

Giorgia Franchin

University of Padua, Padua, Italy

Manabu Fukushima

National Institute of Advanced Industrial Science and Technology (AIST), Nagoya, Aichi, Japan

Dušan Galusek

Alexander Dubček University of Trenčín, Trenčín, Slovakia and Joint Glass Centre of the Institute of Inorganic Chemistry, Slovak Academy of Sciences, Alexander Dubček University of Trenčín, Trenčín, Slovakia

Dagmar Galusková

Alexander Dubček University of Trenčín, Trenčín, Slovakia

Yajie Gao

University of Limerick, Limerick, Ireland

Graziella Goglio

CNRS, University of Bordeaux, Bordeaux INP, Pessac, France

Maurice Gonon

University of MONS, Mons, Belgium

Thomas Graule

Empa, Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, Switzerland and Freiberg University of Mining and Technology, Freiberg, Germany

Sarah Guerin

University of Limerick, Limerick, Ireland

Delia Gutiérrez-Campos

Simón Bolívar University, Caracas, Venezuela

Jens Günster

BAM Federal Institute for Materials Research and Testing, Berlin, Germany and Clausthal University of Technology, Clausthal-Zellerfeld, Germany

Stuart Hampshire

Bernal Institute, University of Limerick, Limerick, Ireland

R.H.J. Hannink

CSIRO Manufacturing Flagship, Clayton South, VIC, Australia

Dominique Hautcoeur

Belgian Ceramic Research Centre, Mons, Belgium

Mathias Herrmann

Fraunhofer Institute for Ceramic Technologies and Systems, Dresden, Germany

David Houivet

Normandy University, UNICAEN, LUSAC, Caen, France

Yuk Ming X Hung-Hung

Simón Bolívar University, Caracas, Venezuela

Hideki Hyuga

National Institute of Advanced Industrial Science and Technology (AIST), Nagoya, Aichi, Japan

Emanuel Ionescu

Technical University of Darmstadt, Darmstadt, Germany

Yuji Iwamoto

Nagoya Institute of Technology, Nagoya, Aichi, Japan

Emilio Jiménez-Piqué

Universitat Politècnica de Catalunya-Barcelona TECH & Barcelona Research Center in Multiscale Science and Engineering, Barcelona, Spain

Suk-Joong L. Kang

Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, South Korea

Hans-Joachim Kleebe

Technical University of Darmstadt, Darmstadt, Germany

Ute Kolb

Johannes Gutenberg University Mainz, Mainz, Germany

Waltraud M. Kriven

University of Illinois at Urbana-Champaign, Urbana, IL, United States

Prashant N. Kumta

University of Pittsburgh, Pittsburgh, PA, United States

Danjela Kuscer

Jožef Stefan Institute, Ljubljana, Slovenia

Stefan Lauterbach

Technical University of Darmstadt, Darmstadt, Germany

Yann Leconte

University of Paris-Saclay, Gif sur Yvette Cedex, France

Anne Leriche

Polytechnic University Hauts-de-France, Valenciennes, France

Jerzy Lis

AGH University of Science and Technology, Kraków, Poland

Tanja Lube

Department of Materials Science, University of Leoben, Leoben, Austria

Daniele Mari

Swiss Federal Institute of Technology Lausanne, Switzerland

D.B. Marshall

Teledyne Scientific Company, Thousand Oaks, CA, USA

P.F. McMillan

University College London, London, UK

John J. Mecholsky, Jr.

University of Florida, Gainesville, FL, United States

Sylvain Meille
University of Lyon, Lyon, France

Gary L. Messing
*Pennsylvania State University, University Park, PA,
United States*

Scott T. Misture
Alfred University, Alfred, NY, United States

Tassilo Moritz
*Fraunhofer Institute for Ceramic Technologies and
Systems, Dresden, Germany*

Günter Motz
University of Bayreuth, Bayreuth, Germany

Martin J. Murtagh
Cornell University, Ithaca, NY, United States

Benoît Naït-Ali
*Institute of Research for Ceramics, University of Limoges,
Limoges, France*

Arnaud Ndayishimiye
Pennsylvania State University, PA, United States

Achim Neubrand
*Fraunhofer Institute for Mechanics of Materials,
Freiburg, Germany*

Tatsuki Ohji
*National Institute of Advanced Industrial Science and
Technology (AIST), Nagoya, Aichi, Japan*

Emel Özel
Eskisehir Technical University, Eskisehir, Turkey

Paola Palmero
*Department of Applied Science and Technology,
Politecnico di Torino, Turin, Italy*

Fabrice Petit
Belgian Ceramic Research Centre, Mons, Belgium

Eliana Pinto-González
Simon Bolivar University, Caracas, Venezuela

Michael Pomeroy
*Bernal Institute, University of Limerick, Limerick,
Ireland*

Jacques Rabier
*Department of Physics and Mechanics, The French
National Centre for Scientific Research, University of
Poitiers, Chasseneuil Cedex, France*

Clive A. Randall
Pennsylvania State University, PA, United States

Wolfgang Rheinheimer
Technical University of Darmstadt, Germany

Marc Rubat du Merac
CeramTec GmbH, Plochingen, Germany

Jan Räthel
*Fraunhofer Institute for Ceramic Technologies and
Systems, Dresden, Germany*

Elvira Saab-Llatas
Simon Bolivar University, Caracas, Venezuela

Maria A. Sainz
*Institute of Ceramics and Glass-Spanish National
Research Council (CSIC), Madrid, Spain*

David Salamon
Brno University of Technology, Brno, Czech Republic

Malika Saâdaoui
*Mohammed V University, Mohammadia School of
Engineering, Rabat, Morocco and Mohammed V
University, Rabat, Morocco*

Robert Schaller
*Swiss Federal Institute of Technology Lausanne,
Switzerland*

George W. Scherer
Princeton University, Princeton, NJ, United States

Sara Serena
*Institute of Ceramics and Glass-Spanish National
Research Council (CSIC), Madrid, Spain*

Hiroyuki Shibata
Tohoku University, Sendai, Japan

Akihiro Shimamura
*National Institute of Advanced Industrial Science and
Technology (AIST), Nagoya, Aichi, Japan*

David S. Smith
*Institute of Research for Ceramics, University of Limoges,
Limoges, France*

Andrew Stewart
University of Limerick, Limerick, Ireland

Sohei Sukenaga
Tohoku University, Sendai, Japan

Ender Suvaci
Eskisehir Technical University, Eskisehir, Turkey

Marcin Szymiczek
*University of Birmingham, Birmingham, United
Kingdom*

Damien Thompson
University of Limerick, Limerick, Ireland

Syed A.M. Tofail
University of Limerick, Limerick, Ireland

Maximilian Trapp
Technical University of Darmstadt, Darmstadt, Germany

Eric R. Twiname
*The Tape Casting Warehouse, Inc., Morrisville, PA,
United States*

Omer Van der Biest
*Department of Materials Engineering, KU Leuven,
Leuven, Belgium*

Navin Venugopal
*Corning Research & Development Corporation, Corning,
NY, United States*

Joaquim M. Vieira
*CICECO-Aveiro Institute of Materials and Ceramic
Engineering, Department of Materials and Ceramic
Engineering, University of Aveiro, Aveiro, Portugal*

S.M. Wiederhorn
*National Institute of Standards and Technology,
Gaithersburg, MD, USA*

Moritz v. Witzleben
INMATEC Technologies GmbH, Rheinbach, Germany

Yu-ichi Yoshizawa
*National Institute of Advanced Industrial Science and
Technology (AIST), Nagoya, Aichi, Japan*

Nur S. Yüzbaşı
*Empa, Swiss Federal Laboratories for Materials Science
and Technology, Dübendorf, Switzerland*

Andrea Zocca
*BAM Federal Institute for Materials Research and
Testing, Berlin, Germany*

VOLUME 1

Overview: Manufacture of Ceramics and Microstructural Developments in Ceramics <i>Francis Cambier and Anne Leriche</i>	1
Synthesis of Oxide and Non-Oxide Advanced Ceramics <i>Prashant N Kumta</i>	2
Synthesis of Ceramic Powders by Wet Chemical Routes <i>Paola Palmero</i>	27
Self-Propagating High-Temperature Synthesis <i>Jerzy Lis</i>	40
Hydrothermal Synthesis <i>Ender Suvaci and Emel Özel</i>	59
Ultrasonic Sprayed Aerosol for Ultrafine Ceramic Powder Synthesis <i>Sylvie Foucaud and Yann Leconte</i>	69
Calcination and Phase Transformations <i>Gary L Messing</i>	83
Preceramic Polymers as Precursors of Advanced Ceramics: The Polymer-Derived Ceramics (PDCs) Route <i>Yuji Iwamoto, Günter Motz, Emanuel Ionescu, and Samuel Bernard</i>	93
Organic Additives in Ceramic Processing <i>Anne Aimable and Thierry Chartier</i>	103
Powder Mixing and Grinding Processes for Ceramics <i>David Houivet and Jérôme Bernard</i>	112
Powder Granulation and Compaction <i>Michele Dondi</i>	136
Colloid Casting Processes: Slip Casting, Centrifugal Casting, and Gel Casting <i>Nur S Yüzbaşı and Thomas Graule</i>	146
Processing of Ceramics by Direct Coagulation Casting <i>Margarida Almeida and Joaquim M Vieira</i>	154
Extrusion <i>Stuart Blackburn and Marcin Szymiczek</i>	162
Ceramic Injection Molding <i>Moritz v Witzleben and Tassilo Moritz</i>	179

Tape Casting and Lamination <i>Eric R Twiname</i>	189
Freeze Casting <i>Dominique Hautcoeur</i>	195
Additive Manufacturing <i>Andrea Zocca, Giorgia Franchin, Paolo Colombo, and Jens Günster</i>	203
Green Machining of Ceramics <i>Fabrice Petit</i>	222
Screen Printing <i>Danjela Kuscser</i>	227
Sintering of Ceramics: An Overview <i>Anne Leriche, Francis Cambier, and Stuart Hampshire</i>	233
Solid-State Sintering <i>John E Blendell and Wolfgang Rheinheimer</i>	249
Liquid Phase Sintering: Fundamentals <i>Suk-Joong L Kang</i>	258
Viscous Sintering <i>George W Scherer</i>	265
Hot Pressing and Hot Isostatic Pressing <i>Mathias Herrmann and Jan Räthel</i>	270
Reaction Sintering <i>Carmen Baudín</i>	278
Flash Sintering and Other Rapid Sintering Techniques <i>David Salamon</i>	286
Spark Plasma Sintering <i>Umberto Anselmi-Tamburini</i>	294
Cold Sintering and Hydrothermal Sintering <i>Graziella Goglio, Arnaud Ndayishimiye, Catherine Elissalde, and Clive A Randall</i>	311
Microwave Sintering of Ceramics <i>Jean-Marc Chaix</i>	327
Porous Ceramics Processing <i>Manabu Fukushima, Akihiro Shimamura, Paolo Colombo, Hideki Hyuga, Tatsuki Ohji, and Yu-ichi Yoshizawa</i>	342
Porous Ceramics Including Fibrous Insulation, Structure and Properties of <i>M Fukushima, T Ohji, P Colombo, and Y-I Yoshizawa</i>	346
Control of the Microstructure in Ceramics <i>Anne Leriche, Stuart Hampshire, and Francis Cambier</i>	349
Templated Grain Growth of Textured Ceramics <i>Gary L Messing</i>	367
Functionally Graded Ceramics <i>Omer Van der Biest and Achim Neubrand</i>	374
Transparent Ceramics: Materials, Processing, Properties and Applications <i>Marc Rubat du Merac</i>	399
Geopolymers and Geopolymer-Derived Composites <i>Waltraud M Kriven</i>	424

Overview: Characterization and Modelling of Ceramics and Glasses <i>Michael Pomeroy and Stuart Hampshire</i>	439
Ceramic Genomics: Total Bond Order Density <i>Wai-Yim Ching</i>	441
Predictive Modeling of Ceramic Materials <i>Sarah Guerin, Syed AM Tofail, and Damien Thompson</i>	475
Molecular Dynamics Simulations of Glass Structure <i>Mattias Edén</i>	481
Computation of Phase Diagrams for Ceramics <i>Sara Serena, Angel Caballero, Antonio H de Aza, and Maria A Sainz</i>	498
Characterization of Ceramic Powders <i>Martin J Murtagh and Navin Venugopal</i>	517
Amorphous Materials: Vibrational Spectroscopy <i>PF McMillan</i>	530
MAS NMR Analysis of Ceramics and Glasses <i>Yajie Gao</i>	536
X-Ray Powder Diffraction <i>Scott T Mixture</i>	549
Case Studies in the X-ray Diffraction of Ceramics <i>Maurice Gonon</i>	560
Introduction to Transmission Electron Microscopy; The Basics <i>Ann-Katrin Fetzer, Maximilian Trapp, Stefan Lauterbach, and Hans-Joachim Kleebe</i>	578
High Resolution Analytical Electron Microscopy of Ceramics and Glasses <i>Jennifer Cookman, Michele Conroy, and Ursel Bangert</i>	600
Introduction to Three Dimensional Electron Crystallography <i>Andrew Stewart and Ute Kolb</i>	618
Preparation of Ceramic, Glass-Ceramic and Glasses for Microstructural Examination <i>Michael J Pomeroy</i>	634
Scanning Electron Microscopy for Ceramics and Glasses <i>Michael J Pomeroy</i>	651
Fractography: Brittle Materials <i>John J Mecholsky, Jr.</i>	662
Thermal Analysis Techniques for Technical Ceramics and Glasses <i>Michael J Pomeroy</i>	676
High-Temperature Characterization of Glasses and Melts <i>Sohei Sukenaga and Hiroyuki Shibata</i>	689
Overview: Mechanical and Physical Properties and Property Testing of Ceramics and Glasses <i>Anne Leriche and Francis Cambier</i>	704
Elastic and Inelastic Behavior of Ceramics <i>Daniele Mari and Robert Schaller</i>	705
Indentation of Ceramics <i>Emilio Jiménez-Piqué</i>	718
Contact Damage Resistance and Tribological Behavior of Ceramic/Carbon Nanostructure Composites <i>Manuel Belmonte</i>	733

Methods of Determination of Young's Modulus and Tensile, Flexural and Compressive Strength <i>Sylvain Meille</i>	745
Fracture Toughness Measurement <i>Tanja Lube</i>	762
R-Curve Behavior of Ceramics <i>Marc J Anglada</i>	775
Subcritical Crack Growth: Basic Relations and Experimental Evaluation <i>Malika Saâdaoui</i>	797
Subcritical Crack Growth: Modeling of the v-K Curve in Different Environments <i>Raul Bermejo</i>	811
Ceramics: Transformation Toughening <i>DB Marshall and RHJ Hannink</i>	818
Mixed-Mode Fracture and Microstructural Aspects of Crack Propagation <i>Delia Gutiérrez-Campos and Yuk Ming X Hung-Hung</i>	823
R-Ratio and Microstructure Effects <i>Delia Gutiérrez-Campos, Eliana Pinto-González, and Elvira Saab-Llatas</i>	841
Thermal Properties of Ceramic Materials <i>David S Smith and Benoît Naït-Ali</i>	855
Thermal Shock Behavior of Ceramics: Fundamentals and Thermal Shock Resistance Parameters <i>Carmen Baudín</i>	867
Thermal Shock and Thermal Fatigue Behavior of Ceramics: Microstructural Effects <i>Gilbert Fantozzi and Malika Saâdaoui</i>	879
Creep Behavior of Ceramics <i>Gilbert Fantozzi and Arturo Dominguez-Rodriguez</i>	891
Nonoxide Ceramics, Creep and Creep Rupture of: Silicon Nitrides and Silicon Carbides <i>SM Wiederhorn</i>	908
Dislocations in Ceramic Materials <i>Jacques Rabier</i>	911
Corrosion of Ceramics in Aqueous Environments <i>Mathias Herrmann</i>	921
Corrosion and Degradation of Glass <i>Dagmar Galusková and Dušan Galusek</i>	932

VOLUME 2

Overview: Oxide Ceramics and Non-oxide Ceramics <i>Stuart Hampshire and Michael Pomeroy</i>	1
Structural and Thermostructural Ceramics <i>Jon Binner and Tammana SRC Murthy</i>	3
Alumina, Structure and Properties <i>Carmen Baudín</i>	25
Low Thermal Expansion Ceramic and Glass-Ceramic Materials <i>Pascal Pilate and Florimond Delobel</i>	47

Mullite: Structure and Properties <i>Gi��le L Lecomte-Nana and Aghiles Hammas</i>	59
Aluminum Titanate, Structure and Properties <i>Salvador Bueno and Carmen Baud��n</i>	76
Zirconia Ceramics, Structure and Properties <i>Anne Leriche, Francis Cambier, and Helen Reveron</i>	93
Si ₃ N ₄ -Ceramics: An Introduction <i>MJ Hoffmann</i>	105
Si ₃ N ₄ Ceramics, Structure and Properties <i>Monika Tatarkov��, Peter Tatarko, and Pavol ��ajgal��k</i>	109
SiALONs and the Representation of Phase Relationships <i>Stuart Hampshire</i>	119
Si-Al-O-N Ceramics, Structure and Properties <i>Ali ��elik and Servet Turan</i>	128
Aluminum Nitride and ALON Ceramics, Structure and Properties of <i>JW McCauley</i>	144
SiC Ceramics, Structure, Processing and Properties <i>Young-Wook Kim and Rohit Malik</i>	150
High Thermal Conductivity Ceramics <i>Mikito Kitayama</i>	165
MAX Phases, Structure, Processing, and Properties <i>Nick Goossens, Bensu Tunca, Thomas Lapauw, Konstantina Lambrinou, and Jozef Vleugels</i>	182
ZrB ₂ , HfB ₂ , OsB ₂ and IrB ₂ Boride Ceramics: Processing, Structure, and Properties <i>Nina Orlovskaya, Holden Hyer, Yongho Sohn, Mykola Lugovy, Gurdial Blugan, Thomas Graule, Jakob Kuebler, Sergey Yarmolenko, Jagannathan Sankar, and Michael J Reece</i>	200
Directionally-Solidified Eutectic Oxide Ceramics <i>VM Orera[†] and J Llorca</i>	216
Overview: High-Performance Ceramics and Ceramic Composites <i>Michael Pomeroy</i>	225
Ceramic Matrix Composites With Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior <i>Gilbert Fantozzi and J��r��me Chevalier</i>	227
Nanoscale Ceramic Composites <i>GS Thompson and MP Harmer</i>	240
Ceramic Matrix Graphene and Carbon Nanotube Composites <i>Katalin Bal��zsi, M��nika Furk��, and Csaba Bal��zsi</i>	243
Short Fiber Ceramic Matrix Composites (SF-CMCs) <i>Walter Krenkel, Stefan Flauder, and Georg Puchas</i>	260
Glass and Glass-Ceramic Matrix Composites for Advanced Applications: Part I: Properties and Manufacturing Technologies <i>Dino Boccaccini, Maria Cannio, Enrico Bernardo, and Aldo R Boccaccini</i>	277
Glass and Glass-Ceramic Matrix Composites for Advanced Applications: Part II: Applications <i>Dino Boccaccini, Maria Cannio, Enrico Bernardo, and Aldo R Boccaccini</i>	288

[†]Deceased.

High Performance Fibers <i>AR Bunsell</i>	304
Spun (Slurry and Sol–Gel) Ceramic Fibers <i>DM Wilson</i>	314
Ceramic Matrix Fiber Composites <i>Francis Rebillat</i>	317
Ultra-High Temperature Ceramic Matrix Composites <i>Luca Zoli, Diletta Sciti, Antonio Vinci, Pietro Galizia, Frédéric Monteverde, Simone Failla, and Laura Silvestroni</i>	340
Carbon-Matrix Composites <i>Deborah DL Chung</i>	353
Ceramics in Space Applications <i>Barry Twomey, Daithi de Faoite, Kevin AJ Doherty, and Kenneth T Stanton</i>	359
Porous Ceramics for Energy Applications <i>Andreas Kaiser, Bhaskar R Sudireddy, and Farid Akhtar</i>	380
Joining of Advanced Ceramics <i>John A Fernie and Kevin M Knowles</i>	393
Abrasives <i>Jean-André Alary</i>	406
Wear and Erosion Resistant Ceramic Materials <i>Pavol Hvizdoš</i>	416
Wear and Erosion Resistant Ceramic Coatings <i>František Lofaj and Marián Mikula</i>	425
Oxidation and Corrosion of Non-oxide Ceramics <i>NS Jacobson and EJ Opila</i>	440
Overview: Glass and Glass Ceramics <i>Stuart Hampshire</i>	445
The Glassy State <i>Maziar Montazerian and Edgar D Zanutto</i>	448
Glasses: Alkali and Alkaline-Earth Silicates <i>Benjamin JA Moulton and Grant S Henderson</i>	462

EDITOR BIOGRAPHIES

Editor In Chief

Michael J. Pomeroy, is Emeritus Professor of Materials Science & Technology at the University of Limerick, Ireland. His education comprised: B. Sc. Chemistry and Materials Science at the University of Wolverhampton, M.Sc. Surface Technology and Management Techniques at the University of Aston and Ph.D. "Corrosion of Alloys in Fluidized Bed Combustion Systems" at the University of Wolverhampton. Following four years as a Researcher in fluidized bed combustion at the University of Limerick, Michael took up a Research position in Silicon Nitride Ceramics. He became an academic at the University of Limerick in 1985. Since then he has carried out research on the oxidation and corrosion of high temperature alloys, metallic coatings and ceramics as well as in the development of silicon nitride and sialon ceramics and related glasses. His more recent research work was related to aluminosilicate glasses containing fluorine and nitrogen, determining how glass structure and properties are affected by cation and anion substitutions. Michael has worked with many

collaborators in Europe, the US and Japan and has collaborated throughout his career with University of Limerick colleague Prof. S. Hampshire. He still collaborates with University and international colleagues on research on glass ceramics and additive manufacturing. Before retirement, Michael developed very successful Masters programs in Biomedical Materials and Advanced Engineering Materials as well as modules in advanced characterization techniques for PhD programs with a taught element. Michael has edited 2 books and was sub-editor of the Reference Module in Materials Science and Materials Engineering (Ceramics section). He has published nearly 200 papers in journals and conference proceedings. He was conferred as a Fellow of the European Ceramic Society in 2017. His spare time is devoted to ringing church bells.

Section Editors

Anne L. Leriche is a ceramist specialising in technical ceramic processing and their microstructure control. She is Professor at Polytechnic University Hauts-de-France. Born in Belgium, she studied at University of Mons (Belgium). She obtained a Masters in Chemistry with honors in 1981. A Post-Graduate grant from Industrial Research Council allowed her to complete her doctorate with honors in 1986 from the State University of Mons, Belgium on "Reactive Sintering of Mullite-Zirconia Composites". During her PhD thesis, she spent time at the Ceramics Department of Leeds University, UK. After a few years as researcher at Belgian Ceramics Research Centre in Mons, she became responsible for R&D in a SME involved in the fabrication of advanced oxide ceramics. In 1990, Anne joined the Ceramic Materials and Processing Lab (LMCPA) at Polytechnic University Hauts-de-France, Maubeuge. In 1994, she was promoted to Professor (full Professor in 2005) and was Director of LMCPA leading 30 researchers from 1999 to 2016. She has supervised 26 PhD

students, managed numerous European projects, published 220 journal or proceedings papers and presented 40 invited lectures. She has served as Board Member of the Belgian Ceramic Society, President of the French Ceramic Society, President of the European Ceramic Society and of the JECS Trust. She is member of the World Academy of Ceramics. In her spare time, Anne likes travelling and takes care of her donkeys and other animals sharing her life in countryside

Carmen Galassi received the degree of Dottore in Industrial Chemistry (*summa cum laude*), Bologna University, 1981. She is Research Fellow at the Politecnico di Milano, Department of Mechanical Engineering and Senior Research Associate at CNR-ISTEC Faenza. Since 1984 she has been a member of the permanent staff at ISTEC, as Researcher, Senior Researcher and Research Director. Her main research interests and expertise are in the development and characterization of ceramic materials with emphasis on ferroelectrics, piezoelectrics and multiferroics. Her main activity was research projects coordination and dissemination, and scientific responsibility of several contracts with industry. She was Coordinator of a network of 11 Laboratories within the EU Program HCM (1995–1997), and two national projects and scientific coordinator of the research Unit ISTEC in several national and EU projects. She participated to the Spin-off Action to establish IPECC srl. Dr Galassi tutored 20 MSC and five PhD students, and has got the National Scientific Qualification as full Professor of Materials Science and Technology in Italian Universities. Out of more than 250 papers co-authored, 185 are published in international, refereed journals and received more than 3000 citations (full list on <https://orcid.org/0000-0002-7892-2836>). She lives in the countryside and likes walking, cooking and travelling.

Francis Cambier received a Masters degree in 1971 and a DSc in 1978, from the University of Mons (Belgium), both in applied chemistry. In 1979 he moved to the Belgian Ceramic Research Centre (BCRC) becoming a research group leader in 1981, Director of Research in 1983 and Director General in 1996. He officially retired from BCRC in July 2017, staying on the board to help his successor. Over 40 years he had the opportunity to develop a broad range of applied research topics in close collaboration with universities and companies all over Europe. His main areas of interest are the manufacturing processes of oxides and non-oxides, their mechanical and microstructural characterization, the application of ceramics in traditional, refractory, structural and biomedical fields. Francis is author or co-author of more than 300 papers, most of them in peer reviewed Journals, has presented more than 350 oral or poster communications, among which about 60 invited. He has always been strongly involved in relations with companies and societies and was board member of several companies and received various awards and distinctions (in Belgium, Germany, Poland, Sweden). A member of the Belgian Ceramic Society, he was its President from 2001–2006. He is a fellow of the American Ceramic Society, and of the European Ceramic Society (ECerS). During many years he oversaw the secretariat of ECerS (2001–2019).

Francis is now president-elect of ECerS (he will be president from 2021–2023) and vice-president of the advisory board of the World Academy of Ceramics. Outside of work he has the very important job of lovingly caring for six grandchildren and 20 vintage cars.

Professor Stuart Hampshire is Professor Emeritus of Materials Science at the University of Limerick, Ireland. Following a first degree from the University of Sheffield in Ceramics Technology, he worked in industry on nitride-bonded refractories before undertaking a PhD at the University of Newcastle on Sintering of Nitride Ceramics. Stuart stayed on as a post-doctoral fellow carrying out research on Oxynitride Glasses which he continued after his appointment at Limerick. He developed the first degree programme in Materials Science, established a research group on ceramics and glasses, collaborating on European-funded projects with other laboratories, and, throughout his career, working with Editor-in-Chief, Professor Mike Pomeroy Stuart was subsequently promoted to full professor in 1996. At that time Stuart was Director of the Materials Ireland Research Centre working with Enterprise Ireland to support Irish industry in areas of Materials Technology. In 1999 he was a founding member of the Materials and Surface Science Institute (now the Bernal Institute) and successfully led the University's proposals for government infrastructure funding of €16 million for new labs and analytical facilities. Stuart has published over 250 papers and given 70 invited

lectures. He is a Fellow of both the American and European Ceramic Societies and a member of the European Ceramic Society Council. He has received various honours including European Ceramic Society Stuijts Award (2007), American Ceramic Society International Bridge Building Award (2008) and an Honorary Doctorate from the University of Limoges, France (2009). The American Ceramic Society Engineering Ceramics Division held a symposium in his honour in 2014. Stuart enjoys classical music and is a member of the Limerick Choral Union.

PREFACE

The Encyclopedia of Materials: Science and Technology was published in 2001 when technical ceramics and glasses were under active development. Since then these materials have seen exponential development and become very important in Industrial sectors related to medical devices, electrical and electronic devices, green energy, automobiles and aerospace. The need for ceramic and glass researchers increased accordingly and will do so in the future. The Encyclopedia of Materials: Technical Ceramics and Glasses (EM-TCG) was therefore conceived to update ceramic and glass related knowledge from the 2001 Encyclopedia and to include chapters covering new materials, processes and applications since that time. The EM-TCG was designed to be, as far as possible, the ultimate source for background knowledge for undergraduate students and early career researchers in ceramics and glasses, written by leaders in the field for the advancement of ceramic and glass science & engineering. A secondary, but equally important objective of EM-TCG was to provide background information for parties interested in the processing, properties and applications of technical ceramics and glasses from a policy or product / process development standpoint. EM-TCG was thus designed to be a solid background information source for a relatively wide audience requiring specialized knowledge in a readily accessible format.

Each of the chapters should help readers readily develop their knowledge base in their specific area. To this end, EM-TCG users should be able to readily access comprehensive, organized, detailed, quality information to support their educational and professional development. This means that in some ways, the encyclopedia could be thought of as a virtual mentor. It is also hoped that early stage researchers and industrial researchers will use EM-TCG as a solid background information source to widen their interest in technical ceramic and glass materials. This can be very important as there are frequent parallels between research areas which appear at face value to be unique and very different.

The subject matter for the Encyclopedia follows a broad schema of processing, materials modeling & characterization, mechanical properties, oxide & non-oxide ceramics, ceramic matrix composites, glasses & glass ceramics, electrical & electronic ceramics and bioceramics & bioglasses. Each of these broad sections has an introductory article which the reader is advised to peruse to get a feel for the section's contents. Whilst not absolutely comprehensive, EM-TCG will thus provide an excellent reference tome. All effort has been made to ensure that the content is wide ranging and detailed. This has been made possible by all of those authors who have made contributions to the encyclopedia. In a few instances, it was decided that some fundamental articles from the original 2001 Encyclopedia should be included as well as some articles more recently contributed to the Reference Module in Materials Science and Materials Engineering.

It must be said that persuading people to write for reference works is not easy because of the reward recognition afforded in terms of career deliverables. This difficulty was further compounded by the Coronavirus outbreak which required many of the authors who had agreed to write having to totally reorganize their day jobs. I am particularly grateful to those authors who had to write and record whole semesters of lecture notes as well as develop new ways of assessing students. To do this as well as contribute to the encyclopedia is highly laudable. I and the Editorial team most heartily thank the nearly 300 authors from across the world who contributed to the 197 chapters in EM-TCG.

I am indebted to the members of the Editorial team whose untiring work beyond the call of duty led to the completion of the Encyclopedia. The Editorial team had as its origins a European Project on Silicon Nitride which began in 1983. Since that time, Prof. Anne Leriche, Prof. Francis Cambier, Prof. Stuart Hampshire and I have collaborated in one form or another. Dr. Carmen Galassi visited Limerick in 1985 for a Conference on Non-Oxide Ceramics and has become well known to the rest of the group since that time. I also thank the people at Elsevier who have helped along the way. Particular thanks must go to Sean Simms and Richard Berryman for their help in smoothing the way from start to finish. Sajana, who seemed able to keep the chapters, authors and editors under control and always be at a computer, deserves very special thanks.

To good ceramic and glass science, good fellowship, fine dining and fine wine - all inseparable!

Michael J. Pomeroy

Ceramics and glass are arguably the oldest materials that man has made. Objects dating back to more than 25,000 years BC have been found. The oldest object is a small statue made of ceramics (fired clay) discovered in 1925 in Moravia (Czech Republic). It is called the “Venus of Dolní Věstonice”. It is a small figurine, representing a nude female. It is remarkable that the Venus de Dolní Věstonice was found broken in two parts, in the middle of ashes. This statue would therefore have been produced using the classical powder → shaping → firing sequence. It was found on the site where it was produced (close to an artisanal oven) and where it was abandoned, it is perhaps also the first witness to the fragility of an incompletely densified ceramics produced from clay.

The processing of ceramics following the classical sequence was continuously improved over time. For many centuries, the use of ceramics has been confined to domestic applications (dishes, containers, etc.) or to luxury and religious objects (jewelry, statuettes, for example). In the nineteenth century, industrialization, the discovery of electricity gradually led to the manufacture of new materials such as refractories, insulators, abrasives. Very quickly the natural source of raw materials revealed flaws and the ceramists realized the need to create advanced raw materials, to imagine innovative manufacturing techniques, to find more efficient consolidation means, and finally to control more strictly every stage of the ceramic materials production process that we call today “technical ceramics”. Empiricism turned into scientific knowledge when the observed phenomena were gradually understood.

This first section of the Encyclopedia of Materials: Technical Ceramics and Glasses is specifically devoted to “*Ceramics Manufacturing and Ceramic Microstructural Development*”. It includes different subsections:

- A. The first part concerns the description of different ways of synthesizing the raw materials developed specifically for the manufacture of technical ceramics. Indeed, such materials must have, on the one hand, an adequate chemical composition with a controlled content of impurities, possibly with specific chemical additions modifying its sintering behavior and the good development of its microstructure and, on the other hand, they must be composed of particles of size, shape, particle size distribution, surface finish, etc. chosen to adapt the raw material to the type of shaping chosen for the industrial manufacture of the green parts and for its subsequent densification.

Seven chapters make up this subsection, the first chapter introduces the various synthesis techniques. Some more specific chapters follow on wet methods, sol gel, SHS technique, hydrothermal synthesis and synthesis with the help of ultrasounds. Most of the methods result in chemical intermediates which must be transformed to obtain the desired composition. A chapter therefore concerns the stages of calcination and phase transformation of raw materials. Finally, some ceramics can be obtained directly from the chemical compound to the finished product: the last chapter of this subsection concerns this type of ceramics.

- B. The second part looks at the steps necessary to obtain the desired shapes in industrial production. In the majority of cases, organic (including polymers) or organo-metallic additives are mixed with the powder raw materials in order to give them an adequate aptitude for shaping. A grinding step may be necessary and/or a granulation step, in particular when the shaping is obtained by compaction. Specific chapters are devoted to forming processes involving dispersion in a solvent (slip, centrifugal, gel casting, direct coagulation process), to those using a viscous paste (extrusion, injection molding, tape casting). Two chapters deal with innovative freeze casting and additive manufacturing techniques. Of course, whenever possible, shaping techniques are tending to achieve a near to net shape object, however, corrections are often necessary, by machining, preferably at the green stage. Finally, some components must be prepared in layers, which is why a chapter is devoted to screen printing.
- C. When the desired shape is achieved, the component must be densified to enhance its integrity. After an introductory chapter describing the principles of the different sintering techniques, three specific chapters give more details on the behavior when no (solid state), a little (liquid phase) or a lot of liquid phase (viscous) is involved in the process. Two other chapters examine the influence of the added pressure and that of the simultaneity of a reaction during densification.

Sintering is a very time consuming and energy intensive process. The objective of a series of recent developments is the reduction of sintering time and therefore of energy consumption. After an introductory chapter giving a brief description of new rapid sintering techniques, more details are given on “Spark Plasma Sintering”, cold, hydrothermal and microwave sintering.

Not all components need full densification. It is particularly the case for ceramics used in a series of applications as catalysts, filters, bioceramic scaffolds, etc., where controlled porosity must be achieved. Two chapters are therefore devoted to porous ceramics.

- D. During the densification process, there is a competition between the disappearance of pores and the unwanted growth of grains. Techniques exist to control the development of the microstructure. They are the subject of a detailed specific chapter.

Two other chapters concern the obtaining of textured and functionally calibrated ceramics. Finally, good examples illustrating the techniques described in the previous chapters for controlling raw materials, shaping, processing, sintering and microstructure are given in the manufacture of transparent ceramics and in the fabrication of geopolymers.

Synthesis of Oxide and Non-Oxide Advanced Ceramics

Prashant N Kumta, Edward R. Weidlein Endowed Chair Professor, Department of Bioengineering, Department of Chemical and Petroleum Engineering, Mechanical Engineering and Materials Science, Center for Complex Engineered Multifunctional Materials (CCEMM); Swanson School of Engineering and Department of Oral Biology, School of Dental Medicine, McGowan Institute of Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States

Introduction

Oxide and non-oxide are universal classifications of ceramics. Oxide or “traditional” ceramics are formed by the reaction of metals with oxygen. These compounds comprise almost 90% of the ceramic materials known today ([Table 1](#)) and constitute a majority of the advanced electronic, structural, optical, magnetic, electrochemical, and biological materials ([Barsoum, 1997](#); [Julien and Nazri, 1994](#); [Lee et al., 2012](#); [Ghadge et al., 2018](#)). Non-oxide ceramics are obtained by reacting a metal, or a semimetal in some cases, with oxygen-free elements such as, S, N, C, B, P, As, Sb, Se, and Te. Unlike oxides, barring diamond and graphitic as well as many of the amorphous carbons, these compounds of non-oxide ceramic systems constitute some of the largest manmade substances. Development of non-oxides have always been slow in progression in comparison to the ubiquitous oxide systems. As a result, the implementation as well as translation to commercially viable products has also been sluggish. The primary barriers to rapid and escalated developments have primarily been due to challenges involved in synthesis and processing of dense structures due to the covalent nature of these systems and also the inherent reactivity of the non-oxygen species particularly, S, Se, Te, P and N to oxygen and moisture even under ambient conditions. The meticulous care needed to process these systems also make it a challenge to develop easily scalable methods to translate the technology from laboratory scale to commercially viable large kilogram scale quantities preserving the purity, microstructure and other attributes to reproduce the desired functionality. Most laboratory scale approaches result in only demonstrating the feasibility of creating a unique configuration or nanoscale architecture such as nanowires, nanotubes, hollow nanotubes, nanodots, nanodroplets, nanoflakes, nanowhiskers etc. At the laboratory scale, these systems demonstrate some very unique and unprecedented properties that has advanced the field of nanotechnology. However, the task of converting these features into the commercial landscape has always proven to be an enormous challenge. Research and advances in manufacturing science has come a long way to overcome many of these hurdles. Nevertheless, striking the right balance between cost and salability while also keeping in mind the attainment of desired microstructure, phase and surface properties to attain the desired functionality is still a challenge requiring more advances to be made. Most of the currently researched non-oxide ceramics belong to the carbide, boride, nitride, and sulfide families whose applications are shown in [Table 1](#) ([Kumta and Risbud, 1994](#); [Srinivasan and Rafaniello, 1997](#); [Jampani et al., 2010](#); [Choi et al., 2006](#); [Kadokia et al., 2014a,b,c](#); [Ghadge et al., 2018](#); [Jampani et al., 2013](#)).

Synthesis of Oxide Ceramics

Oxides as mentioned above are generally stable under normal ambient conditions of atmospheric pressure and temperature, possessing complex structures and exhibiting unusual properties. Several methods described below can and are typically used to synthesize these materials by and large.

Solid-State Approach

This is the conventional and most ubiquitously used method for synthesizing various ceramic materials and consists of mixing and grinding raw materials in a ball-mill or a mortar and pestle. The mixture is then heat-treated at high temperatures to yield the desired ceramic. It is by definition a very convenient and preferred method for synthesizing ceramics, but it suffers from several major limitations. Prolonged high-temperature treatments required to achieve complete conversion and stabilization of the desired phases and microstructure preclude the generation of metastable structures with precise control of grain size, stoichiometry, phase purity, crystal structure, defects and microstructure. Hence the method cannot be used to completely exploit microstructure related properties of the materials. Incomplete conversion and the incorporation of process related contaminants are other factors limiting the methods. The past several years since the original article was published in late 1990 have however witnessed a plethora of efforts to identify alternative approaches for synthesizing oxide ceramics. These approaches and their attributes for various emerging technologies are discussed in the sections to follow.

Chemical-Based Solution Approaches

These methods by definition involve executing chemical reactions conducted at low temperatures (25–100°C) in the presence of a liquid solvent. Inorganic or organometallic salts are generally selected as the primary reactants. The reactions conducted in solution

Table 1 Selected properties and applications of common oxide and non-oxide advanced ceramics

Property	Material class
Electrical and dielectric	SiC, ZrO ₂ , MoSi ₂ , BaTiO ₃ , SrTiO ₃ , etc.; PbZr _{0.5} Ti _{0.5} O ₃ , AlN, Al ₂ O ₃ , β -Al ₂ O ₃ , doped ZrO ₂ , etc.; oxides of Fe, Mn, Co, Bi-doped ZnO, SiC, SnO ₂ , ZnO, etc; ABX ₃ (A = CH ₃ NH ₃ , B = Pb, X = Br, I) Bi ₂ Te ₃ , SnSe; NaPb _m SbSe _{m+2} ; WS ₂ ; MoS ₂
Thermal	SiO ₂ , Al ₂ O ₃ , ZrO ₂ , Al ₂ O ₃ – SiO ₂ , AlN, SiC, diamond
Magnetic	(Ba, Sr)O.6Fe ₂ O ₃ , RE ₂ Fe ₁₇ (Nx (RE = rare earth)), (Zn, M)Fe ₂ O ₃ (M = MnCo, Mg), rare earth garnets, YBa ₂ Cu ₃ O _{7-x} ; MgB ₂
Optical	Soda-lime glass, SiO ₂ , CaLa ₂ S ₄ , ZnS, γ -La ₂ S ₃ , BaF ₂ , GeS ₂ , Al ₂ O ₃ , MgO, Y ₂ O ₃ , Mn:ZnS, CaWO ₄ Zn ₂ SiO ₄ :Mn, LiNbO ₃ , As ₂ S ₃ , Ge – Sb – S; GeS ₂ – La ₂ S ₃
Chemical	Cordierite (2MgO.2Al ₂ O ₃ .5SiO ₂), Mo ₂ N, W ₂ N, TiS ₂ , SiC

phase result in excellent molecular-level mixing of the various components an aspect not attainable in solid-state techniques. In addition, selection of the appropriate precursors and control of the reaction chemistry can help to generate amorphous precursors containing molecular level coordination and composition similar to those observed and desired in the final ceramic. Good control of the structure, phase, and microstructure of the particles can thus be achieved. Excellent mixing at the molecular level also promotes diffusion at scales of ≈ 100 Å enabling high-temperature materials to form at moderate ($< 1000^\circ\text{C}$) temperatures, hence enabling preservation of many microstructural and phase related features including stabilization of metastable phases critical for achieving certain functionality. There are several chemical-based methods.

- (1) *The sol – gel method.* This is the most popular method for synthesizing oxide ceramics and glasses with the ability to achieve varying degrees of control of stoichiometry, phase purity, and microstructure. Since its applicability for ceramics was first demonstrated by Roy (1956), it has become the hallmark method for synthesizing a variety of oxides and soon emerging for generating non-oxide as well. The approach is based on hydrolyzing metal alkoxides followed by polymerization and condensation to yield amorphous metal oxides. The use of myriad catalysts, complexing agents, drying control additives, and different types of solvents alter the kinetics of these reactions leading to the generation of extremely fine nanostructured particles of equilibrium and non-equilibrium phases exhibiting unique morphologies. Common complexing agents include acetic acid and β -diketonates including other electron donating chelating agents. These complexing agents control the reactions, thereby increasing the gel time and controlling the particle size while also varying the extent of the polymerized chains in the gel solution, rendering it amenable for dip and spin-coating to form oxide films. At the solution level by controlling and delaying the reaction kinetics, the technique also makes it amenable for spraying and vaporizing to generate epitaxial growth via exploitation of thin film techniques such as metal-organic chemical vapor deposition (MOCVD). The approach over the years in particular, since the emergence and dominance of nanotechnology has clearly emerged as the most viable method of choice for synthesizing a vast range of ceramics and glasses for electronic, optical, magnetic, and electrochemical applications. Several articles and texts provide an exhaustive description of the process and its applications (Brinker and Scherer, 1990; Thomas, 1988; Wood and Dislich, 1995). While traditional sol – gel approaches involve the use of metal alkoxides, factors of cost, polymeric nature, reactivity, and moisture sensitivity of alkoxides have led to the identification of alternative non-alkoxide-based approaches for synthesizing materials without losing the characteristic favorable and desirable sol – gel attributes. In this vein, development of the particulate sol – gel (PSG) approach for synthesizing LiNiO₂, a lithium-ion electrode (Chang et al., 1998) is a good example of a nonalkoxide process. The oxide is obtained by the reaction of LiOH and Ni(CH₃COO)₂ in the presence of water and methanol. A gel is formed by the presence of Ni(OH)(CH₃COO) species undergoing OH – OCH₃ exchange. Fig. 1 shows the SEM images of the PSG derived precursor, the transformed, nanosized (≈ 100 nm) LiNiO₂, and the solid state-derived Li₂CO₃. The reaction between the large-grained solid-state derived Li₂CO₃ and NiO is kinetically hindered yielding a defective and an incompletely transformed, electrochemically inferior LiNiO₂, whereas excellent mixing of the intermediate nanocrystalline Li₂CO₃ and NiO (Fig. 2) products formed by virtue of the molecular level mixing in the PSG process results in the formation of defect-free stoichiometric LiNiO₂ with good and desirable electrochemical properties of specific capacity and cycle life. This approach indeed has the potential for generating high Ni containing high energy density lithium transition metal oxide cathodes extensively researched at present. While the approach demonstrates retention of many of the attributes of typical metal alkoxide derived sol-gel process, there have been attempts to explore non-hydrolytic approaches. Thus, in 1992 Goel et al. (1992) showed that oxides can be made by non-hydrolytic sol-gel process using acetone as the condensation agent via an aldol-condensation-elimination reaction sequence. They demonstrated this approach by reacting Zn alkoxides with acetone in benzene resulting in mesityl oxide and ZnO. The mesityl oxide is formed via the aldol condensation mechanism where in carbonyl compounds dimerize forming β -hydroxyketones that dehydrate resulting in α , β – unsaturated carbonyl compounds. The stability of the gels is however, limited

Fig. 1 SEM micrographs showing the morphology of commercial lithium carbonate: (a) decomposed PSG-derived xerogel sample; (b) at a magnification of 20 kX; (c) LiNO_2 obtained after heat treatment at 750°C for 5 h.

shrinking with time to form precipitates. Subsequent to this approach, [Acosta et al. \(1994\)](#) demonstrated formation of oxide gels via a non-hydrolytic sol-gel process through the reaction of an aluminum alkoxide with corresponding halide salt to form the oxide gel releasing alkyl halide. Alumina gels were obtained by conducting the reaction in the $70\text{--}110^\circ\text{C}$ temperature range. Calcination in air at 600°C resulted in alumina with loss of the volatile hydrocarbons showing another approach to generating oxides without the normal hydrolysis and condensation of metal alkoxides.

- (2) *Colloidal precipitation.* This is a classical method for synthesizing several crystalline and amorphous metal oxides. The procedure consists of solubilizing the inorganic or organometallic salts of any desired metal in an aqueous or non-aqueous solvent followed by hydrolysis using strong inorganic hydrolyzing agents that tend to be strong electrophiles as well as alkaline bases such as NH_4OH or NaOH . In most cases, the immediately generated precipitated hydroxides depending on the concentration are heat-treated to yield the oxides. In some cases such as barium titanate, oxalate precipitates derived from a solution of chlorides or nitrates are decomposed to form the oxide ([Reed, 1988](#)). Precipitation is induced when the solubility product, K_{sp} is exceeded. The precipitation approach has been exploited extensively earlier on by Matijevic as reported by [Ellis and McNamara \(1989\)](#) for synthesizing a vast array of uniform dispersions of homogeneous and monosized particles of oxide and nonoxides that could be isolated or even self-assembled into unique colloidal architectures. The kinetics of the reactions are controlled to induce uniform growth of a single burst of nuclei yielding spherical particles with a narrow size distribution in the range of $0.5\text{ }\mu\text{m}$.
- (3) *Intercalation and ion exchange.* These are important approaches that have evolved over the years and has become synonymous with generation of high surface area layered structures by exfoliation for synthesizing several layered compounds and involve hosting a variety of guest molecules in the cavities, channels, or interlayer spaces of host oxides and sulfides ([Rao, 1994](#)). Many of these reactions are topochemical governed by orientation relationships rather than involving major changes in crystal structures. The unique feature of ion-exchange and intercalation would be to preserve the host crystal structure. Characteristic intercalation reactions are those popularized in the Li-ion battery field dominated by lithiated transition metal oxides LiMO_2 ($\text{M} = \text{Ni}, \text{Co}, \text{V}, \text{and Mn}$). Insertion and removal of Li^+ results in alteration of the oxidation state of the transition metal leading to an electrochemical potential which is the basis for lithium-ion batteries. Ion exchange is also effective in yielding new oxides as seen in $\beta\text{-Al}_2\text{O}_3$ ($\text{Na}_2\text{O} \cdot n\text{Al}_2\text{O}_3$, $n = 5\text{--}11$) and NaMnO_2 where other cations in the former and lithium in the latter can exchange sodium. The approach has also been used to insert Li^+ into graphitic anodes for Li-ion batteries.
- (4) *Hydrothermal and solvothermal processes.* These are powerful methods for synthesizing oxides and involve reactions that occur in the presence of a solvent under supercritical conditions or close to such temperature – pressure domains ([Demazeau, 1999](#)).

Fig. 2 (a) Diffraction pattern of the decomposed PSG-derived xerogel sample corresponding to Li_2CO_3 and NiO ; (b) corresponding bright field image; (c) dark field image of lithium carbonate taken at the same region as shown in the bright field image; (d) dark field image corresponding to nickel oxide.

The physicochemical properties of the solvent under varying temperature and pressure can be used to alter diffusion of chemical species resulting in the stabilization of novel structures that are difficult or not obtained via standard techniques. The term “hydrothermal” is given to reactions performed in the presence of water (Lencka and Riman, 1993). A variety of ferroelectric oxides [$\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$], spinels (LiMn_2O_4), giant magnetoresistant oxides ($\text{La}_{0.5}\text{Ba}_{0.5}\text{MnO}_3$), and phyllosiloxides ($\text{KMg}_2\text{AlSi}_4\text{O}_{12}$), a new class of bi-dimensional oxides, has been obtained by this method. The approach has grown over the years and used now routinely to generate unique metastable microstructures such as nanotubes and nanowires of a variety of oxides (Ghadge *et al.*, 2018; Patel *et al.*, 2016)

- (5) *Topochemical methods.* These methods are based on executing reduction and oxidation reactions conducted on the parent system leading to a homologous series of compounds (Rao, 1994). The reactions are governed by inducing orientation changes in the parent oxide. Examples can be seen in LaNiO_3 and LaCoO_3 wherein the formation of the homologous series $\text{La}_n\text{B}_n\text{O}_{3n-1}$ ($\text{B} = \text{Ni, Co}$) is observed by reduction of the parent oxide LaBO_3 ($\text{B} = \text{Ni, Co}$) in hydrogen. The parent oxide is recovered by oxidation. The high-temperature superconductor phase, $\text{YBa}_2\text{Cu}_3\text{O}_7$ can be reduced to $\text{YBa}_2\text{Cu}_3\text{O}_6$ by a similar topochemical reaction. A similar topochemically induced relationship is observed in the transformation of the perovskite-like phases of various manganites $\text{Ca}_2\text{Fe}_{2-x}\text{Mn}_x\text{O}_{6-y}$ ($y < 1$), belonging to the homologous series $\text{A}_n\text{B}_n\text{O}_{3n-1}$ ($n = 3$; $\text{A} = \text{Ca, Fe}$; $\text{B} = \text{Mn}$), to the brownmillerite structures. Similar approaches are popular in the catalysis field.
- (6) *Thermal decomposition of precursors.* This approach is suitable for synthesizing mixed metal oxides by decomposition of a single solid precursor containing all the individual components (Rao, 1994). A major advantage is the reduced diffusion distances of the multiple ions due to the generation of the solid precursor via solution approaches. Thus thermal decomposition of $\text{LaCo}(\text{CN})_6 \cdot 5\text{H}_2\text{O}$ and $\text{LaFe}(\text{CN})_6 \cdot \text{H}_2\text{O}$ in air readily yields LaCoO_3 and LaFeO_3 . Similarly, BaTiO_3 and LiCrO_2 can be obtained by decomposing the precipitated oxalates $\text{Ba}[\text{TiO}(\text{C}_2\text{O}_4)_2]$ and $\text{Li}[\text{Cr}(\text{C}_2\text{O}_4)_2(\text{H}_2\text{O})_2]$. Single-phase solid solutions of the monoxides $\text{Mn}_{1-x}\text{M}_x\text{O}$ ($\text{M} = \text{Mg, Ca, Co, or Cd}$) possessing the rock-salt structure are also obtained by decomposition of the isostructural carbonates of the metals. Similarly, ternary and quaternary oxides of the perovskite and the brownmillerite families can be obtained. Perovskite and related oxide structures containing mixed metals can also be obtained by decomposing hydroxide, nitrate, and cyanide solid solutions.
- (7) *Pechini process.* This method has been exploited over the years by several researchers and is as popular as the sol-gel process and has been used for synthesizing over 100 mixed metal oxides including lanthanum manganite for solid oxide fuel cells and BaTiO_3 that was first popularized by Lessing (1989). Unlike the sol – gel process in which the metal alkoxide creates alkoxy moieties participating in the gel forming reactions, this process is also based on a gelation reaction primarily induced

by a polymeric esterification reaction between the alcohol and acid used as solvents. A polymeric resin containing a good distribution of cations is thus obtained which yields the oxide upon calcination. The use of polyacrylic acid with higher functionality results in highly cross-linked resins containing a more uniform distribution of the reacting cations. The gel structures can be easily and conveniently varied depending on the acid-to-alcohol ratio. A low organic content is however preferred to decrease the calcination time and temperature in order to obtain fine-grained materials with low carbon contents and high purity. The presence of carbon can also be tailored depending on the application requiring improved transport of surface charges especially in the field of supercapacitors discussed later.

- (8) *Microemulsion techniques.* The approach is based on the immiscibility of organic liquids (oils) and water resulting in droplets. An oil-in-water emulsion is generated if the first liquid is oil and the second is water, and water-in-oil if the sequence is reversed. Macroemulsions are turbid due to the large droplet size ($> 1 \mu\text{m}$). Microemulsions on the other hand, are thermodynamically stable and are transparent, created by modifying the oil and water interface using surfactants. The droplets are smaller than $0.15 \mu\text{m}$. A water-in-oil microemulsion or a reverse micelle microemulsion contains hydrocarbon chains with their polar heads pointing inwards. The central portion is the aqueous phase in which inorganic reactions can be conducted to yield several oxides (Osseo-Assare and Arriagada, 1990). Alteration of the pH can result in folding of the micellar regions to form microtubules. Sol – gel reactions conducted around the cylindrical micelles after calcination lead to oxide tubules. Mesoporous SiO_2 (MCM-41) has been obtained in this fashion which has been popularized over the years for catalytic applications (Kresge *et al.*, 1992).
- (9) *Other techniques.* Several modified approaches have emerged, some of which include spray pyrolysis and aerosol decomposition. In these methods the clear sol containing colloidal particles or a clear solution of metal salts can be easily atomized to form droplets through an atomizer that can be then pyrolyzed by leading the aerosol droplets into a furnace to yield metal oxides. Nebulization leads to a mist or an aerosol containing fine-sized droplets that are decomposed to form oxides. Transparent conducting oxides (e.g., SnO_2) (Chawla *et al.*, 1983) and other oxides have been obtained in this fashion. The approach has also been universally adopted for a variety of oxides.

Other techniques include mechanochemical approaches (Gaffet *et al.*, 1999) based on high-energy mechanical milling of oxide precursors to yield nanostructured solid solutions. A variety of oxides such as mullite, calcia and yttria-doped ZrO_2 , zircon and Al_2O_3 , ZrO_2 , $\text{ZrO}_2 - \text{MgO}$ solid solutions, and LiMO_2 ($\text{M} = \text{Ni, Co}$) has been obtained. Other methods include self-propagating high-temperature combustion and flame synthesis methods to yield oxides. The former involves sustained use of an exothermic oxidation reaction typically initiated by an ignition step which sets up instantaneously, a combustion front that assists in the reaction. The latter is an extension of combustion involving the oxidation of SiCl_4 and AlCl_3 to yield oxides (Lin *et al.*, 1999; Chung *et al.*, 1990). The approach received significant attention due to the ability to create extremely fine particles in the nanometer range.

Emergent techniques

Over the years, since 2000, there have been improvised methods of chemical and solution based approaches to generate various oxide systems for a variety of applications. These range from electrodes for supercapacitors to framework materials for rechargeable lithium ion batteries, electrocatalysts for proton exchange membrane (PEM) based fuel cells (PEMFCs) utilizing hydrogen derived from electrolysis of water as well as the recently emerging field of perovskite based solar cells including biomaterials and delivery systems for tissue engineering and regenerative medicine. These advances have also stemmed from the emergence and growing developments in the field of nanotechnology.

Supercapacitors: The field of supercapacitors until 2000 was largely dominated by the concept of double layers and surface adsorption of electric charges. Thus, carbon based systems demonstrating the ubiquitous electrical double layer was the primary phenomenon behind the electric double layer capacitors (EDLC) wherein the ability of protons and hydroxyl ions as well as other cations and anions present in electrolytes to adsorb to high surface area electrodes was the primary source for charge storage. However, with the emergence and the recognition of lithium-ion intercalation and ability to cycle Li-ions in host systems, the concept of incorporating ions exhibiting multi-valence states and the accompanying oxidation and reduction (redox) of the cations contributing to charge storage in addition to surface active states presented by the high surface area substrate gave rise to the field of pseudo-capacitors and the coining of the term, supercapacitors for systems exhibiting very high ability to store charge capitalizing on the system undergoing Faradaic redox reactions combined with high surface area. Thus, the system driven largely by noble metal based oxides such as high surface area RuO_2 as well as transition metal non-oxides became immensely popular in the mid-2000 and beyond (Jampani *et al.*, 2010; Choi *et al.*, 2006). Crystalline RuO_2 and amorphous $\text{RuO}_2 \cdot n\text{H}_2\text{O}$ are well-known pseudocapacitors that are well-studied exhibiting specific capacitance as high as 350 F/g and 720 F/g, respectively. The high capacitance follows from the redox activity presented by Ru via proton adsorption in acidic electrolyte. Despite the high cost of RuO_2 , it has been studied extensively since Ru presents the ability to undergo a variety of oxidation states (II-IV) while also exhibiting very good electronic conductivity ($\sigma_{\text{bulk}} = 2.8 \times 10^6 \text{ S/m}$). Crystalline and amorphous RuO_2 are largely synthesized by chemical approaches involving mixing aqueous solutions of NaOH and $\text{RuCl}_3 \cdot x\text{H}_2\text{O}$. The base, NaOH was added to mainly adjust the pH to a value of ~ 7 , to initiate controlled precipitation. Crystallinity was controlled by annealing the precipitated hydrous oxide at elevated temperatures (Hu *et al.*, 2004; Zheng and Jow, 1995).

Beginning in 2000 and beyond until the resurgence of lithium ion systems, supercapacitor systems utilizing multiple oxidation states of transition metals was a targeted focus. In this connection to combat the cost of precious group metals, effort was directed to vanadium. Accordingly, VN and V_2O_5 were explored as charge storage systems. In the latter case, the approach was to exploit the

Fig. 3 Scanning electron microscope images of (a) VACNT; (b) Vanadium oxide thin film; (c) CVD deposited vanadium oxide – VACNT architectures.

electronic conductivity of a substrate to serve as the carrier to house the nanoparticles of the transition metal oxide. In this regard, the well-known electronic and mechanical compliance characteristics of carbon nanotubes was heavily exploited. For example, [Jampani et al. \(2013\)](#) utilized a facile two-step chemical vapor deposition (CVD) approach to synthesize carbon nanotube (CNT) supported vanadium oxide nanoparticles as a heterostructured composite architecture to serve as electrochemical supercapacitors. The high electronic conductivity of CNTs was exploited to provide a facile 3-D electron transport channel on which the vanadium oxide nanoparticles interact with the electrolyte to demonstrate superior supercapacitor response in aqueous media. They have shown that nanoparticulate droplets of vanadium oxide deposited on CNTs exhibit excellent capacitance values as high as 1400 F/g with acceptable rate capability and excellent charge retention up to 200 cycles. They used nickel disks on which vertically aligned carbon nanotubes (VACNTs) were deposited following an approach wherein a mixture of ferrocene in m-xylene was used as the carbon source with ferrocene acting as the catalyst for CNT nucleation and growth. The mixture following vaporization was led into a hot wall CVD reactor maintained at 700°C. A low temperature atmospheric pressure CVD (APCVD) setup was used to generate vanadium oxide nanoparticles directly on the vertically aligned carbon nanotubes. To generate the vanadium oxide nanoscale droplets, vanadium chloride, VCl_4 and distilled water were used as precursors that were evaporated and carried into the hot wall CVD reactor wherein the CNT coated Ni disks were placed. Deposition to generate the vanadium oxide nanoparticles on the vertically aligned CNT was conducted at 450°C for 45 min. **Fig. 3** shows the scanning electron microscope collected image of vertically aligned CNTs deposited by chemical vapor deposition on Ni substrate. The oxide deposited is in the form of 0.2–0.5 μm diameter spheres which cover the length of the CNT at regular spacing between each spherical particle allowing for maximum electron transport through the CNT-oxide interface minimizing transport through the oxide grain boundaries enabling fast charge transfer of the stored charge. The nanospherical morphology also affords increased surface exposure of the oxide to the electrolyte thus maximizing the electrochemical surface area resulting in optimal capacitance response.

[Jampani et al. \(2015\)](#) further studied the influence of doping of Ti into the VACNT derived vanadium oxide nanoscale droplets in a subsequent publication showing the improved electronic conductivity of the Ti-doped vanadium oxide nanospheres on

Fig. 4 SEM image of (a) CVD derived VACNTs coated with Ti doped vanadium oxide showing VACNT forests and (b) Ti-doped vanadium oxide coated CNTs grown by CVD.

VACNT in the form of a semi-contiguous film comprising of ~ 250 nm diameter amorphous Ti-doped vanadium oxide ($V_{1.6}Ti_{0.4}O_{5-x}$ with $x \sim 0.4$) globules (Fig. 4) similar in morphology to those seen in Fig. 3. The doping of Ti was achieved by using $TiCl_4$ and VCl_4 dissolved in an aprotic solvent of chloroform recovered in a sealed stainless steel evaporator bottle. The doped vanadium oxide nanospheres were deposited on the VACNTs using a hot wall tubular atmospheric pressure CVD similar to undoped vanadium oxide. Deposition was carried out at 250°C for 20 min. The Ti-doped vanadium oxides results in an order of magnitude improvements in electronic conductivity compared to the undoped counterparts. The increase in electronic conductivity induced by the introduction of the dopant via the CVD process coupled with the anchoring of the doped oxide nanoparticles to the carbon nanotube is expected to increase the electron transport and hence, result in enhanced supercapacitor performance (Jampani *et al.*, 2015).

Electrocatalysts: Over the last decade or so, there has been intense activity in the area of electrocatalysts for acid mediated proton exchange membrane (PEM) based fuel cells and water electrolysis for generating hydrogen to drive the PEM-based hydrogen fuel cells. Iridium oxide (IrO_2) has been the gold standard platinum group metals (PGM) metals based electrocatalyst. The standard method for generating IrO_2 has been the Adams catalyst synthesis approach based on the oxidative reduction of the salts of platinum group metals. Modification of the Adams synthesis approach has been attempted to generate high specific surface area IrO_2 ($\sim 191\text{ m}^2/\text{g}$) electrocatalyst followed by doping with fluorine. Fluorine contents of 5, 10, 15 and 20 wt% were incorporated into the oxide to improve the electronic conductivity. The approach consisted of reacting iridium tetrachloride [$IrCl_4$] and ammonium fluoride [NH_4F] in stoichiometric amounts dissolved in deionized water (D.I.). The solution containing these dissolved salts were then reacted with excess sodium nitrate also in D.I. water to generate the corresponding nitrate precursors with vigorous stirring for 2 h followed by evaporation to remove the water at 60°C and then subsequently, heat treating the nitrate mixture to 500°C for 1 h to generate the high specific surface area F-doped IrO_2 powders. The F-doped IrO_2 nanoparticles generated by Kadakia *et al.* (Fig. 5) show the $\sim 5\text{--}10$ nm sized particles of $IrO_2:10\text{ wt\% F}$ electrocatalyst of specific surface area $\sim 157\text{ m}^2/\text{g}$ (Kadakia *et al.*, 2014a,b,c).

Following the demonstration of F-doped IrO_2 , there have been several studies to generate reduced PGM containing electrocatalysts and also PGM-free oxide electrocatalysts. Accordingly, tin oxide containing reduced amount of Ir maintaining the solid solution of tin oxide and the same lattice registry was generated. Similarly, manganese oxide containing reduced amount of Ir also maintaining solid solution of manganese oxide and iridium oxide were synthesized to demonstrate similar electrocatalytic performance as the parent IrO_2 . Keeping in line with the hypothesis of reducing the noble metal content while preserving the crystal structure of the parent oxide and thereby result in a solid solution, first attempted to generate solid solutions of IrO_2 containing tin oxide accompanied by fluorine doping. Correspondingly, they synthesized $SnO_2:10\text{ at\%F}$ containing only 20 at% IrO_2 to form $(Sn_{0.80}Ir_{0.20})O_2:10F$ to demonstrate robust electrocatalytic performance of acid mediated proton exchange membrane based oxygen evolution reaction (OER) electrocatalysts. They generated the solid solution oxide electrocatalyst by dissolving the respective chloride salts of Ir and Sn along with NH_4F as the source for fluorine. Stock solutions corresponding to $IrCl_4$ and $SnCl_2 \cdot 2H_2O$ of the desired compositions were dissolved in absolute ethanol. Ammonium fluoride was dissolved in an ethanol-water mixture. The stock

Fig. 5 High resolution TEM image of $\text{IrO}_2:10 \text{ wt\% F}$ particles showing the nanostructured nature of the electrocatalysts.

solutions of the fluoride and the oxide were mixed to generate the $(\text{Sn}_{0.80}\text{Ir}_{0.20})\text{O}_2:10\text{F}$ electrocatalyst by spin coating on pretreated titanium substrates at a rotating speed of 500 rpm for 10 s. The spin coated films were dried at 60°C for 2 h and then thermally treated at 400°C for 4 h in air to decompose the precursors and form the solid solution oxide electrocatalyst composition containing fluorine as the doped anion. **Fig. 6** shows the SEM micrograph along with X-ray mapping of Ir, Sn, and O (**Fig. 6(a)**) and EDAX (**Fig. 6(b)**) of the $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2:10\text{F}$ film. The SEM image along with the elemental x-ray mapping (**Fig. 6(a)**) combined with EDAX (**Fig. 6(b)**) of the representative area of the $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2:10\text{F}$ film containing 10 wt%F indicates the presence of the typical “mud crack” features of the oxide coated film on the Ti foil (**Fig. 6(a)**) confirming the presence of Ir, Sn and O homogeneously distributed within the oxide film particles. The bright field TEM image of the film (**Fig. 6(c)**) shows presence of fine nanometer size ($\sim 10\text{--}15 \text{ nm}$) particles corresponding to the solid solution composition of $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2:10\text{F}$.

Subsequent to the successful demonstration of the excellent electrocatalytic activity for OER of the solid solution thin film generated of composition of $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2:10\text{F}$ that is indeed comparable or even better than pure IrO_2 OER catalyst considered as the gold standard, the group also followed by generating nanostructured powders of the same solid solution composition. They observed that $(\text{Ir}_{0.3}\text{Sn}_{0.7})\text{O}_2:10 \text{ wt\% F}$ displayed electrochemical activity for oxygen evolution reaction in acid mediated PEM based conditions comparable to commercially obtained pure IrO_2 demonstrating a reduction of $\sim 70 \text{ mol\%}$ in the noble metal content (*Kadakia et al., 2014a,b,c*). The powders were generated by using a surfactant based template approach. A mixed amphiphilic surfactant cetyl trimethylammonium bromide (CTAB) is dissolved in de-ionized (D.I.) water to which 6 wt% ammonium hydroxide is added. After homogenization, a solution of tin chloride hydrate dissolved in D.I. water is added which results in a white slurry. To introduce fluorine, NH_4F dissolved in D.I. water is added after the addition of the tin chloride. The resultant solution is aged at room temperature for 48 h after vigorous stirring for 4 h. The precipitate obtained is filtered and dried in an oven at 50°C followed by heat treatment in air at 300°C resulting in fluorine doped SnO_2 . To prepare the iridium tin oxide solid solution, IrCl_4 was dissolved in ethanol along with the required amounts of the as-prepared F-doped SnO_2 . The solution was dried in an alumina crucible in an oven for 60°C for 3 h and then subjected to heat treatment in air at 400°C for 4 h to form the $(\text{Ir}, \text{Sn})\text{O}_2:\text{F}$ solid solutions. **Fig. 7** shows the bright field TEM image of the undoped and 10 wt% F doped $(\text{Ir}_{0.3}\text{Sn}_{0.7})\text{O}_2$ nanoparticles.

In line with synthesis of the solid solution of Sn containing iridium oxide, the researchers also explored solid solution of RuO_2 with 80 at% SnO_2 [e.g., $(\text{Sn}_{0.8}\text{Ru}_{0.2})\text{O}_2:10\text{F}$] synthesized by a very similar approach displaying remarkably similar electrochemical activity and moreover, even comparable or much improved electrochemical stability and durability compared to the undoped and pure noble metal equivalent oxide, RuO_2 . They prepared the solid solution oxide using ruthenium chloride, RuCl_3 and tin chloride, SnCl_2 dihydrate with ammonium fluoride as the starting precursors (*Kadakia et al., 2014a,b,c*). Stock solutions corresponding to RuCl_3 and $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ of the desired composition were dissolved in absolute ethanol along with use of NH_4F dissolved in ethanol-deionized water mixture of 5:1 vol ratios. They spin coated the mixture of the chlorides and the fluoride at a speed of 500 rpm for 10 s followed by drying at 60°C for 2 h after which they were thermally heat treated at 450°C for 4 h in air to decompose the precursors and generate the solid solution electrocatalyst. **Fig. 8** shows the SEM image with x-ray mapping of the Ru, Sn and O in the $(\text{Sn}_{0.8}\text{Ru}_{0.2})\text{O}_2:10\text{F}$ film. The TEM image also similar to the Ir system shows the presence of fine nanoparticles.

Efforts were also focused on generating vertically aligned nanorods of the reduced precious group metal containing electrocatalysts. Keeping in line with this theme and trying to exploit the nanoscale aspects to achieve improved electron and ion transport, the team of *Chadge et al. (2018)* explored and first reported the synthesis of vertically aligned $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2:10\text{F}$ nanotubes showing excellent electrocatalytic activity for acid mediated oxygen evolution reaction (OER) superior to IrO_2 thin film. They generated the nanotubes by first generating ZnO nanowires as a sacrificial template on Ti foils by the hydrothermal method. Zinc acetate solution in ethanol was spin coated on cleaned Ti substrates at 500 rpm for 40 s and then heated to dry at 125°C . The Ti foil containing the zinc acetate layer was then subjected to heat treatment in air at 340°C for 20 min which resulted in the seed layer of ZnO on the Ti foil. To grow the ZnO nanowire template, the Ti foiled containing the ZnO seed layer was placed in a sealed container- enclosing the growth solution of zinc nitrate hexahydrate,

Fig. 6 SEM micrograph and x-ray mapping of Ir, Sn and O (a) and EDAX (b) of the $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2\cdot 10\text{F}$ film. (c) Bright field TEM image of film showing nanoparticles in the film.

hexamethylenetetramine, polyethyleneimine and ammonium hydroxide. The sealed container was placed in a water bath, preheated to 90°C for 6 h. The formed nanowires were then carefully washed with ethanol and D.I. water followed by drying at 50°C for 6 h.

The tin oxide nanotubes, SnO_2 NTs were generated using the ZnO nanowires template by placing the ZnO nanowires grown Ti substrate in an aqueous solution of 3 ml of 0.15 M ammonium hexafluorostannate with 1 ml of 0.5 M boric acid and 1 ml of D.I. water at 26°C for 30 min. In this process, the ZnO nanowire template on Ti substrate is replaced with the SnO_2 nanotubes retaining the pre-formed vertically aligned morphology of ZnO. Following the generation of the SnO_2 NTs, the Ti substrate containing the SnO_2 NTs were placed in a solution of IrCl_4 and ammonium fluoride in DI water corresponding to the composition of $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2\cdot 10\text{ wt}\% \text{F}$. The Ti substrate containing the SnO_2 NTs infiltrated with IrCl_4 and NH_4F solution was then subjected to heat treatment at 400°C for 4 h to form the $(\text{Sn}_{1-x}\text{Ir}_x)\text{O}_2\cdot 10\text{F}$ vertically aligned nanotubes (VANTs) on Ti foil. The entire synthesis scheme is shown in Figs. 9 and 10 shows the morphology and elemental mapping analysis of the synthesized $(\text{Sn}_{0.8}\text{Ir}_{0.2})\text{O}_2\cdot 10\text{ wt}\% \text{F}$ VANTs.

The above is a demonstration of how chemical synthesis approaches were utilized to generate solid solutions of mixed oxide elements to generate effective electrocatalysts for OER in acid mediated PEM based water electrolysis. In line with the overall aims to reduce the precious group metal contents, efforts have also been directed to synthesize highly efficient and robust electrocatalysts that are completely devoid of any noble or precious metal contents. The group embarked on exploiting spinel oxides containing the base structure of manganese oxides with incorporation of copper to generate the spinel oxides along with doping the oxide solid solution with fluorine to induce improvements in electrical conductivity needed to match these systems with precious group metals such as Pt and IrO_2 . Exploiting density functional theory (DFT) as with the other systems discussed above, Patel *et al.* (2016) identified and synthesized $\text{Cu}_{1.5}\text{Mn}_{1.5}\text{O}_4\cdot 10\text{F}$ as an effective spinel electrocatalyst showing excellent activity for OER as well as oxygen reduction

Fig. 7 Bright field TEM image of (a) $(\text{Ir}_{0.3}\text{Sn}_{0.7})\text{O}_2:10 \text{ wt\% F}$, and (b) undoped $(\text{Ir}_{0.3}\text{Sn}_{0.7})\text{O}_2$ showing the nanometer sized fine particles generated by the template approach.

reaction (ORR) in acid mediated PEM based systems. They synthesized the high surface area nanoparticles of $\text{Cu}_{1.5}\text{Mn}_{1.5}\text{O}_4:10\text{F}$ by exploiting a template approach. First, they synthesized nanoparticles (NPs) of MnO_2 by taking manganese acetate tetrahydrate dissolved in 25 ml of DI water. To this solution, KMnO_4 was added with vigorous stirring immediately resulting in the formation of a brown precipitated slurry. The precipitate was collected by filtration and then thoroughly washed by DI water followed by drying at 60°C for 2 h which formed amorphous MnO_2 nanoparticles which gave a specific surface area of $\sim 150 \text{ m}^2/\text{g}$. The $\text{Cu}_{1.5}\text{Mn}_{1.5}\text{O}_4:10\text{F}$ NPs were generated by soaking the as-synthesized MnO_2 NPs in stoichiometric amounts of copper chloride dehydrate achieved by dissolving $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ in 25 ml of DI water followed by addition of as-synthesized MnO_2 NPs. To generate the F doped oxide, $\text{Cu}_{1.5}\text{Mn}_{1.5}\text{O}_4:10\text{F}$, again stoichiometric amount of ammonium fluoride (NH_4F) was dissolved in 5 ml of DI water to which was added stoichiometric amount of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ (20 ml) solution with stoichiometric amount of as synthesized MnO_2 NPs. The solution of the MnO_2 NPs along with the solution of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ and NH_4F was dried in an alumina crucible in a drying oven at 60°C for 2 h followed by heat treatment in air at 500°C for 4 h. They generated $\text{Cu}_{1.5}\text{Mn}_{1.5}\text{O}_4: x \text{ wt\% F}$ with different F contents ($x = 0, 5, 10, 15$) with $\text{Cu}_{1.5}\text{Mn}_{1.5}\text{O}_4:10\text{F}$ exhibiting the best OER and oxygen reduction reaction (ORR) response under acid mediated PEM conditions. **Fig. 11** shows the schematic of the synthesis approach and morphology of the synthesized spinel NPs.

Synthesis of electrocatalyst systems discussed thus far has focused on acid mediated PEM based electrolysis and fuel cells. However, there has also been sufficient interest in identifying, developing and synthesizing electrocatalysts in the neutral and alkaline conditions as well. [Kanan and Nocera \(2008\)](#) for example demonstrated that by electrodepositing cobalt phosphate on indium tin oxide, they were able to demonstrate good electrocatalytic activity for water splitting under neutral conditions. The electrodeposited electrocatalyst film of potassium containing amorphous cobalt phosphate ($\text{Co}_3(\text{PO}_4)_2$) in **Fig. 12** shows the typical mud-crack morphology similar to that seen under spin coating discussed above.

Similarly, [Suntivich et al. \(2011\)](#) showed that $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCF) catalyzes the OER reaction with intrinsic electrochemical activity that is at least an order of magnitude higher than the state of the art iridium oxide electrocatalyst in alkaline media. They prepared the BSCF electrocatalyst using glycine nitrate combustion approach wherein alkaline earth and transition metal nitrates were prepared in water to which glycine was added at 0.1 M concentration. The mixture was heated with vigorous evaporation followed by calcining at 1100°C in air for 24 h to generate the BSCF electrocatalyst. **Fig. 13** shows the XRD pattern of the BSCF electrocatalyst.

Biomaterials: The field of biomaterials has been largely dominated by biodegradable polymers with the approval granted by Food & Drug Administration (FDA) to the use of biodegradable polymers, such as polycaprolactone (PCL), poly-L-lactic acid (PLLA) and polyglycolic acid (PGA) as well as co-polymers of PLLA and PGA, namely poly-L-lactic-co-glycolic acid (PLGA). The use of calcium phosphates (CaPs) is well documented in the literature ([Lee et al., 2012](#)) primarily for use as scaffolds and delivery systems. In fact, one of the earliest uses of CaPs in the form of particulates has been as a control system for non-viral gene delivery. However, in early 2000 and even later on, [Olton et al. \(2007\)](#) showed for the first time that with control of the concentration of the reactants without the use of any toxic surfactants, it is possible to generate uniform, nano-sized, mono-dispersed CaP nanoparticles complexed with plasmid DNA (pDNA) under physiological conditions. They generated the CaP nanoparticles which they appropriately called nanostructured calcium phosphates also abbreviated and termed as NanoCaPs by reacting the Ca-salt, CaCl_2 with a phosphate precursor, Na_3PO_4 along with the base such as NaOH chosen suitably to ensure that the pH during the whole process remains above neutral to ensure hydroxyapatite formation but stable at physiological pH of 7.4 critical to cellular function and viability. As a result the process was executed thus maintaining the pH greater than 7 to consistently generate stoichiometric hydroxyapatite $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ under physiological conditions. Moreover, when they synthesized NanoCaPs by adding pDNA to $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ and then adding the pDNA complexed $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ to an equal volume of phosphate precursor solution at pH 7.5 in a controlled manner using a syringe pump at a set flow rate of $13.4 \mu\text{l/s}$, the resultant precipitation reaction leads to condensation of the plasmid DNA forming condensed and complexed form of NanoCaPs-pDNA complexes. These NanoCaPs-pDNA nanoparticulate complexes in the range of 25–50 nm in size (**Fig. 14**)

Fig. 8 SEM micrograph combined with x-ray mapping of elements (a), and EDAX (b) of $(\text{Sn}_{0.8}\text{Ru}_{0.2})\text{O}_2:10\text{F}$ film. could serve as efficient carriers of pDNA for non-viral gene transfection. Following this demonstration, there have been several developments of use of CaPs as scaffolds in mineralized tissue engineering. The development of injectable bone cements using NanoCaPs as well as CaP systems combined with biodegradable polymers has demonstrated efficacy for releasing growth factors and antibiotics (Roy *et al.*, 2016). Roy *et al.* prepared the cements by mixing the CaP cement precursor with NanoCaPs solution in a polystyrene pour boat. The cements would set at 25°C and 37°C with an initial set time of 9 min and final setting time of 25 min at 25°C. At physiological temperature of 37°C, the initial setting time would reduce to 7 min with a final setting time of 19 min. With the addition of PLGA polymer of particle size 40 µm, the initial and final setting times were measured to be 10 min at 28 min at 37°C. The PLGA-CaP cement made by adding a resorbable calcium phosphate (ReCaPP) cement to PLGA serves as an effective delivery systems as well as forms a porous cement (Fig. 15) that will undergo resorption when implanted thus serving as an effective drug, growth factor as well as an efficient and very safe non-viral gene delivery systems capable of delivering the required payloads and dosage while also acting as promising resorbable scaffolds for mineralized tissue engineering applications. The synthesis of this composite is a demonstration of how effectively a composite cement can be made using an oxide ceramic such as CaP along with a degradable polymeric

sphere that can together serve to bind and contain various antibiotics, growth factors as well as plasmid DNA for controlled release of the bound growth factor, DNA and drug. At the same time, the resorbable nature of the entire composite makes it also an effective scaffold with and without the polymer for mineralized tissue engineering particularly for growing and regenerating bone for patients afflicted with traumatic orthopedic bone injuries requiring a scaffold to fill a segmental bone defect exceeding the critical size beyond which the body loses its inherent ability to heal and regenerate bone.

Synthesis of Non-Oxide Advanced Ceramics

Synthetic efforts have thus far been directed at few popular systems such as SiC , TiN , AlN , Si_3N_4 , TiC , Mo_2C , ZnS , CaLa_2S_4 , Mo_2N , $\gamma\text{-La}_2\text{S}_3$ and TiB_2 . There has been some unique interest in ternary nitrides (DiSalvo, 1990) due to their novel electronic and

Fig. 13 XRD pattern of $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCF) electrocatalyst.

magnetic properties. Over the years there has been significant interest in transition metal carbides, nitrides and sulfides including borides as well as composites of B, C, and N for a variety of insulating, electronically conducting, electromagnetic shielding, unique electronic switches as well as semiconducting properties particularly of layered systems as discussed in the sections to follow. Common and nonconventional methods used to obtain non-oxides are also discussed below.

Solid-State Approach

This is the most common method used to synthesize non-oxides ([Srinivasan and Rafaniello, 1997](#)) very similar to oxides and involves carbothermal reduction at high temperatures in excess of 1500°C in the presence of nitrogen to form compounds such as AlN , Si_3N_4 , TiN , NbN , SiC , TaC , NbC , B_4C , TiC , WC , and ZrC . Borides, TiB_2 , TaB_2 , and ZrB_2 are also synthesized by the reaction of the corresponding oxides of transition metal and boron with carbon acting as a reducing agent. As noticed, the reactions are requiring of very high temperatures owing to the inertness of nitrogen and carbon, much higher than that typically needed for oxides. Direct reaction of sulfur with metals has also been used traditionally to obtain sulfides (e.g., TiS_2) ([Sriram and Kumta, 1998](#)). The solid-state process has been used to explore several ternary nitrides (LiMoN_2 , $\text{Co}_3\text{Mo}_3\text{N}$, $\text{Fe}_3\text{Mo}_3\text{N}$, FeWN_2 , etc.) due to their interesting properties. Alkali metals, being electropositive, help to stabilize the transition metal and the higher oxidation state of nitrogen in the solid-state reaction of alkali metal nitrides and transition metal nitrides as outlined by DiSalvo. Ternary nitrides have also been obtained by ammonolysis of the mixed metal oxides or the mixed metal powders as well as nitridation of sulfides ([Marchand et al., 1999](#)).

Fig. 15 The SEM images at different magnifications of PLGA-ReCaPP-40 cement aging at 37°C for different time periods (a) 0 day, (b) 6 days, (c) 15 days, (d) 15 days at high magnification showing the PLGA film on the cement, (e) 30 days and (f) 30 days at high magnification showing CaP crystals formation, (g) 30 days showing interconnected porosity of macropores, (h) 30 days at high magnification showing the presence of platelet like morphology and (i) 30 days at high magnification showing formation of nanostructured CaP. Solution-Based Wet Chemistry Techniques

The advantages of chemical techniques as articulated for the case of the oxide ceramics earlier have also led to extensive studies in the area of non-oxide ceramics of which many have involved the heat treatment of sol – gel-derived oxides in ammonia, carburizing, or sulfidizing atmospheres to generate metal nitrides, carbides, or sulfides. These methods using the pre-synthesized oxide provide the advantages inherent to chemical techniques at least for generating the oxides favoring the rapid conversion to the non-oxide due to the higher chemical reactivity afforded by the high surface area nature of the pre-synthesized oxide precursor, although complete conversion to the non-oxide still entails prolonged annealing at elevated temperatures. In parallel, studies have also focused on pyrolysis of organometallics or polymers to synthesize a variety of nitrides and carbides. In the case of transition metals, these methods entail the reaction of tetrakisdiakylamido compounds of transition metals with amine reagents such as ethylenediamine (Seyferth and Mignani, 1988) to yield polymeric complexes, resulting in the metal nitride, carbide, or carbonitride after pyrolysis in NH_3 . Thermolysis of borazine, and other variations of the compound, has been used to obtain BN (Rüssel and Seibold, 1994; Gonsalves and Xiao, 1994). Methods have also been improvised to generate soluble polysilazane precursors, which are converted to the desired nitride by spray pyrolysis in the presence of ammonia (Mizutani and Liu, 1990). Solid and liquid polysilazanes of differing hydrocarbon content are synthesized by reacting chlorosilanes with ammonia. The sol – gel process has also been applied to synthesize directly sulfides and nitrides. This involves direct replacement of the alkoxy groups of alkoxides by thiol and amino groups in solution using sulfidizing and nitriding agents. The approaches have been called the thio-sol-gel and hydrazide sol-gel processes (Sriram and Kumta, 1998; Kumta *et al.*, 1999). The advantage is the ability to form metal-sulfur and metal-nitrogen bonds directly in the solution level by the direct replacement of the alkoxy groups by hydrosulfide and hydrazide species in the solution stage itself. The direct replacement results in gels depending on the alkoxide and the solvent, although complete replacement is difficult due to the polymeric nature of the alkoxide and the lower electronegativity of the hydrosulfide, amine and hydrazide species compared to the hydroxyl ions. Nevertheless, the gels have significant amounts of the non-oxide anions, and hence conversion of the alkoxy-non-

oxide precursor to the corresponding non-oxide occurs at moderate temperatures while also inheriting the advantages of molecular level mixing and nanoscale porosity to result in porous high surface area materials. The method has been used successively to synthesize non-oxides of reactive group IIIA, transition, and rare-earth metals. The incomplete replacement is advantageous since unique nano-crystalline microstructures can be achieved exhibiting interesting electrochemical properties. Alkoxides have also been used to synthesize silicon oxycarbide glasses, called "black glass", by sol – gel reactions of alkyltrialkoxysilanes (Zhang and Pantano, 1990). Metal – alkyl links create metal – carbon bonds in these glasses when pyrolyzed resulting in metal oxycarbides which are refractory exhibiting high temperature insulating properties for use in thermally resistant composites. These very same approaches to create the metal-non-oxygen linkages in the precursor stage via alkoxy-thiol or alkoxy-hydrazide or creating a polymeric precursor containing the metal-carbon or metal – nitrogen or metal-boron linkages to convert to the desired non-oxide at moderate temperatures has also been utilized to create mesoporous ordered structures by incorporating templates. These approaches are discussed below and consequently, such structures have tremendous applications in variety of areas of electrocatalysis, energy storage, conversion as well as electromagnetic shields and emerging fields of sensing etc.

Other Approaches

Other vapor-phase related approaches exist particularly for synthesizing silicon nitride via plasma and aerosol decomposition (Anderson *et al.*, 1989). The process consists of initiating a reaction between SiH_4 and NH_3 in a high-frequency plasma. The resulting amorphous powders containing largely silicon diimide and hydrogen yield the nitride upon calcination providing the thermal energy in appropriate environments. Improved processes using low temperatures and low pressure assisted plasma have also been developed for controlling the stoichiometry and purity of the nitride. Solvothermal reaction has also emerged as an attractive process for synthesizing nitrides and sulfides by executing reactions between metal or metal salts and sulfidizing or nitriding agents in non-aqueous solvents at modified temperatures and pressures in an autoclave (Demazeau, 1999). Several nitrides Mo_2N , GaN, TiN, and C_3N_4 , sulfides In_2S_3 , CdS, PbS, etc., and selenides and tellurides of Pb and Bi (Yu *et al.*, 1998) have been obtained in this fashion.

Metal salts and nitriding or sulfidizing agents in polar solvents directly precipitate nitrides and sulfides. The reaction can be controlled to generate a homogeneous distribution of uniform particles in the case of ZnS (Guiton *et al.*, 1988) or to yield nanostructured nitrides (Sriram *et al.*, 1995). Metathetic reactions of metal chlorides or organometallics and various nitriding agents such as liquid ammonia, hydrazine, hexamethyldisilazane, and amines or sulfidizing agents in suitable solvents result in nanostructured nitrides (Narula and Allard, 1998) or sulfides. Thus AlN, Si_3N_4 , GaN, TiN, ZrN, TiS_2 , CdS, ZnS, BN, etc. have all been successfully obtained in this manner. Mechanochemical milling, a direct extension of the well-known high energy mechanical milling approach, by milling metals with carbon and NH_3 yields nanostructured SiC (Yang and Shaw, 1996), Si_3N_4 , and GaN (Li *et al.*, 1998; Millet and Calka, 1995). Borides (e.g., TiB_2), and $\text{Sn}_2\text{Fe}/\text{SnFe}_3\text{C}$ (Mao *et al.*, 1999) and Si/TiN (Kim *et al.*, 2000) nanocomposite anodes for Li-ion cells have also been obtained. The success of this approach has been extensively utilized in subsequent years by various researchers to also generate other nanoscale composites of Si with inert non-oxide ceramics such as SiC, TiB_2 including carbon as alternative anodes to traditionally used carbon in lithium ion batteries.

Chemical complexation (Weil and Kumta, 1997) and electrochemical reactions (Rüssel and Seibold, 1994) are other methods to generate nitrides. The former are effective for obtaining powders and films, and are based on use of chelating metal chlorides in organic solvents initially which helps to shield the precursors from attack by moisture which would normally occur. The direct consequence of this shielding effectively provided by use of various low and high molecular weight chelating agents as well as the control of concentration of chelating agents is the ability to form stable complexes that yield unique ternary nitrides (CrWN_2 , $\text{Ni}_3\text{Mo}_3\text{N}$, $\text{Ni}_2\text{Mo}_3\text{N}$) after pyrolysis in NH_3 . The latter yield metal nitrides (AlN, TiN, Ti(C,N) , ZrN) by anodic dissolution and oxidation of metals while reducing organic electrolytes such as propylamine or acetonitrile to obtain polymers, which after pyrolysis yield nitrides or carbides. Similar to solution based approaches, these methods above can also be used to generate mesoporous ordered structures by executing the above reactions in the presence of a template as discussed in the section to follow.

Emergent techniques

Since 2000, there has been significant developments in the field of non-oxide ceramics as well similar to the advances witnessed in the field of oxide ceramics. These developments have been commensurate with advanced technologies and applications requiring the use of next generation non-oxide ceramics. The developments have come into vogue primarily with the intense research and evolution of the field of nanotechnology very similar to the area of oxide ceramics discussed above. Some of these advances in processing arises from the exploitation of chemistry principles to generate non oxide ceramics via oxide free sol-gel processes.

As outlined in the nice review by Hector (2007), is the oxide free sol-gel approach, an approach that has gained much notoriety especially in the field of silicon nitrides different from the use of alkoxides to form sulfides via the thio-sol-gel and the hydrazide sol-gel process used in principle for synthesizing transition metal sulfides and nitrides discussed above. One of the common approaches was the straightforward approach of ammonolysis of dialkyl aminosilanes with ammonia followed by condensation to make the imide ($-\text{NH}-$) linkages very similar to the hydrolysis and condensation reaction observed in alkoxides. A problem with use of non-oxygenated species is the extreme reactivity to moisture and air requiring the process to be handled under extreme care and under inert conditions. In relation to this, the common and well established approach was that developed by Bradley by condensation of metal dialkyl amides by first forming an amide precursor that would undergo condensation without the need for ammonolysis in the beginning to generate

Fig. 16 X-ray diffraction pattern of Ti(C, N) coatings heat treated at different temperatures.

the nitrides. Zheng *et al.* with Mackenzie later exploited this approach for metal dialkyl amides to undergo aminolysis and polymerization reaction with primary amines to form metal nitrides (Zheng *et al.*, 1992). They used this approach to generate coatings of titanium carbonitride as well as TiN. They would take the soluble precursors formed via the reaction of metal dialkyl amides with primary amines to dip coat suitable substrates such as silicon followed by heat treatment in nitrogen at 500°C prior to each dip to generate the coatings before firing at elevated temperatures up to 1000°C in N₂ for 1 h to generate the metal carbonitride coatings (Fig. 16). Another approach popularized for silicon carbide and carbonitride was the approach by Kroke and Riedel (Balan *et al.*, 2000). They generated silicon carbodiimide gels via the reaction of bis(trimethyl silyl)carbodiimide with chloro(organo)silanes as shown below resulting in polymeric silicon based carbodiimide gels which can be pyrolyzed to generate silicon carbonitride. The approach is quite flexible and can be used to link other metals via the use of metal halides to react with the bis(trimethyl silyl)carbodiimide.

Similar approaches were used to generate hexagonal boron nitride by reacting cyclic chloroborazines with hexamethyl disilazane as shown in Fig. 17 to form gels that transformed to glassy solids on solvent removal. Pyrolysis of these solids in ammonia would form hexagonal boron nitride (*h*-BN). Similar approaches have been used to generate B/C/N materials with composition close to B₄CN₄ when pyrolyzed at 1200°C giving pure B₄C at 1800°C.

Many of the advances in the field of non-oxide ceramics can also be discussed in connection with the relevant technologies similar to the advanced oxide ceramics earlier as under.

Supercapacitors: As in the case of oxide ceramics above, transition metal non-oxides were identified as emergent materials in 2006 for advancing the field of supercapacitors. This was primarily by virtue of exploiting the variable oxidation states afforded by transition metals allowing the ability to harness multiple redox couples with various electronic transitions akin to ruthenium oxide discussed in the oxide ceramics. One notable example here is the work by Choi *et al.* (2006) wherein they showed that nanostructured VN synthesized by a two-step ammonolysis approach would have promising supercapacitor response matching and even exceeding that of the precious metal group counterpart of RuO₂·xH₂O. They generated the nanostructured nitride by reacting the dissolved chloride salt in anhydrous chloroform with anhydrous ammonia to generate chloroamide precursors that were then heat treated in anhydrous ammonia to 400°C then passivated with flowing 0.1% oxygen containing ultra-high purity Ar at room temperature for 4 h to generate oxygen passivated nitrides. The resultant nanocrystalline nitrides of specific surface area ~38.8 m²/g shown in Fig. 18 exhibit excellent supercapacitor response with capacitance as high as 1340 F/g for the first time which exceeded that of ruthenium oxides.

Thermoelectrics: In a recent article by Slade *et al.* (2019) they have shown that alloys of PbSe and NaSbSe₂ represented as NaPb_mSbSe_{m+2} or NaSbSe₂ + mPbSe are a new class of materials for thermoelectric applications exhibiting a maximum figure of merit, ZT of 1.4 near 900K when properly doped. These compounds were however, synthesized by normal solid state approaches, the novelty being the generation of a new class of systems. The approach involved batching elemental Pb wire, Se shot, Sb shot, and Na cubes in stoichiometric amounts after removing oxide layers on the surface of Pb and Na into carbon coated fused silica tubes which were flame sealed at ~2 × 10⁻³ Torr. The tubes were heated in a box furnace to 773K over 12 h, held for 2 h, and then heated to 1473K for over 7 h and then held for 5 h. The tubes were then quenched in ice water with annealing at 773K for 12 h. After these treatments, the ingots were recovered, ground to a fine powder and then sintered into dense pellets by spark plasma sintering. Fig. 19 shows the TEM and EDS analysis of the Na_{1.15}Pb_{0.85}SbSe₁₂ synthesized by the above approach.

Fig. 17 Chloroborazine cross-linking induced by reaction with hexamethyldisilazane.

Fig. 18 High resolution TEM images of (a) nanocrystalline VN agglomerates and (b) VN nanocrystals obtained at 400°C in NH₃.

Solar cells: Since 2009, there has been extensive interest in perovskite solar cells based on methyl ammonium lead triiodide (CH₃NH₃PbI₃) and phenomenal progress has been documented (Nazeeruddin and Snaith, 2015). The systems have been synthesized using various techniques of precursor solution deposition, two-step sequential deposition, dual-source vapor deposition, and vapor-assisted solution processed techniques. In particular, Zhou *et al.* (2015) synthesized the CH₃NH₃PbI₃ material by vapor assisted solution process (VASP) technique. This includes first deposition of the inorganic framework by a solution approach and subsequently, the in-situ reaction of the inorganic species of PbI₂ with the desired organic vapor of CH₃NH₃I at 150°C with time scaling up to 4 h as shown in Fig. 20. The perovskite film obtained using this VASP technique and the characteristics of the film obtained are shown in Figs. 21 and 22.

Layered carbides sulfides and nitrides: Layered transition metal dichalcogenides (TMDs) have been studied (Chhowalla *et al.*, 2013) recently for their technological interest as electrocatalysts for hydrogen evolution, hydrosulfurization as well as electrically active materials for opto-electronics. Some of these systems include MoS₂, WS₂, TiS₂, TaS₂, ZrS₂ and NbSe₂. These systems are synthesized

Fig. 19 (a) Characteristic high-resolution TEM image of a $\text{Na}_{1.15}\text{Pb}_{9.85}\text{SbSe}_{12}$ and (b) selected area electron diffraction pattern, confirming a clean rocksalt structure with no evidence of any nanoscale precipitates. (c) Backscattered electron image showing noticeable Z contrast and (d) – (g) EDS elemental maps over the region shown in (c). The EDS maps confirm that there were minor elemental segregation into Pb rich and Na/Sb rich regions.

Fig. 20 Schematic of the two-step vapor treatment approach for generation of dense, continuous perovskite thin film.

by chemical vapor deposition (CVD) and chemical exfoliation of the bulk material by top-down and bottom-up approaches (Wang *et al.*, 2012). Top-down methods involve peeling of atomically thin layers of TMDs from parent bulk crystals by micromechanical cleavage using adhesive tape. The method is however, not scalable. Exfoliated nanosheets by liquid phase separation is promising. Intercalation of lithium ions into TMDs by n-butyl lithium for more than a day to allow Li ions to intercalate followed by exposing the intercalated TMDs to water causing removing of Li between the layers evolving hydrogen gas rapidly separating the layers. Another approach is ultrasonication in appropriate liquids including organic solvents, aqueous surfactant solutions or solutions of polymers in solvents. Bottom up approaches involve the use of CVD to generate wafer scale synthesis of TMDs in the form of large area single crystals via epitaxy. TMDs have also been generated by hydrothermal synthesis in an autoclave or reaction of molybdic or tungstic acid with thiourea or selenourea at elevated temperatures to form the corresponding TMD material. These approaches are shown in Fig. 23. As shown in the figure, are described methods for synthesizing TMD layers (a) Stable suspensions of layered materials from liquid-phase exfoliation in solvents (top) and thin films derived from vacuum filtration of the suspensions (bottom), (b) suspension of Li-intercalated and exfoliated MoS_2 in water (left). High-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) image of MoS_2 (middle) from suspensions in the left panel and atomic force microscopy (AFM) image of MoS_2 flakes deposited on SiO_2 (right). White line is a height profile taken at the red line position. Inset in the middle panel is magnified view of HAADF-STEM image showing honeycomb arrangement of MoS_2 . Green and yellow dots represent Mo and S. Scale

Fig. 21 Perovskite film on fluorine doped tin oxide substrate by VASP: (a) top-view SEM image (inset: higher resolution image scale bar = 1 μm); (b) cross-sectional SEM image of the film.

Fig. 22 (a) The $\text{PbI}_2/\text{CH}_3\text{NH}_3\text{PbI}_3$ film at the intermediate stage at 0.5 h (inset: wider view, scale bar = 3 μm) and (b) the $\text{CH}_3\text{NH}_3\text{PbI}_3$ film at the post-stage at 4 h.

bar 0.5 nm. (c) CVD schematic of MoS_2 from S and MoO_3 (left) forming MoS_2 films on SiO_2 (right). Red dots are furnace heating elements. Optical microscopy image show MoS_2 in lighter regions and darker regions are silica. (d) CVD of MoS_2 from solid Mo on SiO_2 exposed to S vapor (top left) giving MoS_2 layers visible in optical microscopy (right). Bottom left: side-view schematic of an MoS_2 layer on Si/SiO_2 substrate. (5) CVD of MoS_2 from dip-coated precursor on substrate and growth in Ar gas and S vapor.

Similar to TMDs, another system that has gained popularity since its identification in late 1990s are transition metal containing silicon and aluminum nitrides and carbides. In 2011, Barsoum *et al.* identified a new class of 2D transition metal carbides and nitrides, they labeled as MXenes (Anasori *et al.*, 2015). The term was given due to the ability to selectively etch the A layers from the 3D layered parent compounds, the $\text{M}_{n+1}\text{AX}_n$ or MAX phases where M is an early transition metal, A is an A group element such as Al or Si and X is carbon and/or nitrogen and $n = 1-3$. To date, MXenes synthesized are $\text{Ti}_3\text{C}_2\text{T}_x$, Ti_2CT_x , V_2CT_x , Nb_2CT_x , $\text{Nb}_4\text{C}_3\text{T}_x$. Here, T_x represents surface groups of O, OH, and F. Other MXenes with other M elements such as Sc, Zr, Hf and Mo have also been predicted by the team. They synthesized the MAX phases by ball milling of Mo, Ti, Al and graphite powders for 18 h using zirconia balls in plastic jars to form $\text{Mo}_2\text{TiAlC}_2$ and $\text{Mo}_2\text{Ti}_2\text{AlC}_3$, respectively with molar ratios of Mo/Ti/Al/C of 2:1:1:2 for the former and 2:2:1.3:2.7 for the latter. Powder mixtures were then heated in covered alumina crucibles at $5^\circ\text{C}/\text{min}$ to 1600°C and held for 4 h under flowing argon. After cooling the porous structures were milled using a TiN coated milling bit producing powders of $\text{Mo}_2\text{Ti}_2\text{AlC}_3$ phase. $\text{Cr}_2\text{TiAlC}_2$ was synthesized by heating elemental mixtures of Cr, Ti, Al and C at 1500°C for 1 h under Ar flow. To

AFM image of MoS₂ flakes on SiO₂. White light is height profile. Inset is magnified HAADF-STEM image. (c) Schematic of CVD of MoS₂ (d) CVD growth of MoS₂ from S vapor and Mo on SiO₂. (e) CVD of MoS₂ from dip-coated precursor on substrate and growth in Ar gas and S vapor.

generate the MXene phases, 2 g of Mo₂TiAlC₂ or Mo₂Ti₂AlC₃ powders was added over ~60 s, to 20 ml of 48%–51% aqueous HF solution and held at ambient temperature (55 °C for Mo₂Ti₂AlC₃) for 48 h (90 °C for Mo₂TiAlC₂) with stirring followed by washing 5 times with distilled water and then centrifuging at 3500 rpm for 120 s with final decantation. The pH of the supernatant was maintained greater than 6. The final product was then mixed with distilled water and filtered on a membrane to generate the layered carbide structures. Fig. 24 shows the synthesis and structure of Mo₂TiC₂ and Mo₂Ti₂C₃. (a) Shows the XRD patterns of the Mo₂TiAlC₂ phase before (red) and after (green) HF treatment and after delamination (blue). In the delaminated state, only the c-direction peaks, (00l) peaks are seen corresponding to a, c – lattice parameter of 30.44 Å; the (110) peak is not observed, thus showing loss of order in non-basal direction. (b) XRD patterns of Mo₂Ti₂AlC₃ before (pink) and after (purple) HF treatment and after delamination (black). (c) and (d) show the schematics of Mo₂TiAlC₂ to Mo₂TiC₂T_x and Mo₂Ti₂AlC₃ to Mo₂Ti₂C₃T_x transformations, respectively; the red and green, blue and black circles correspondingly represent Mo, Ti, Al and C atoms, respectively. (e) and (f) are SEM images of Mo₂TiAlC₂ and Mo₂TiC₂T_x, respectively. Note the layers become more open after etching in Mo₂TiC₂T_x (g) and (h) show the HRSTEM images of Mo₂TiAlC₂ and Mo₂TiC₂T_x, respectively. Atoms are shown with the same colors as in (c). Atomic ordering is confirmed by EDAX mapping. No Al is observed in the EDAX analysis of Mo₂TiC₂T_x (i) Lower magnification TEM image of (f) showing the layered structure throughout the sample. (j) and (k) are SEM images of Mo₂Ti₂AlC₃ and Mo₂Ti₂C₃T_x, respectively. HRSTEM images of (l) Mo₂Ti₂AlC₃ and (m) and (n) Mo₂Ti₂C₃. Atoms are shown with the same colors as in (d).

Mesoporous Non-Oxides: Similar to the oxide field, there has been considerable activity in the area of synthesis of ordered mesoporous non-oxide materials (Shi *et al.*, 2011). Shi *et al.* have reviewed and discussed various approaches outlined by reviewers in generating ordered mesoporous inorganic non-oxide materials having interest in a variety of applications in catalysis, energy conversion, storage, electronic transport, shielding, etc. due to their unique properties. Most of the approaches are very similar to those followed in oxide ceramics and those outlined above. These include hard-templating (nanocasting) and soft-templating (surfactant assembly) methods. The major issues in these approaches involve template composition, mesostructured, pore surface

Fig. 24 Synthesis and structure of Mo_2TiC_2 and $\text{Mo}_2\text{Ti}_2\text{C}_3$ systems. (a) XRD patterns of $\text{Mo}_2\text{TiAlC}_2$ before and after HF etching and after delamination. (b) XRD patterns of $\text{Mo}_2\text{Ti}_2\text{AlC}_3$ before and after HF treatment and after delamination. (c) and (d) show the schematics of the transformation from $\text{Mo}_2\text{TiAlC}_2$ to Mo_2TiC_2 and $\text{Mo}_2\text{Ti}_2\text{AlC}_3$ to $\text{Mo}_2\text{Ti}_2\text{C}_3$, respectively. (e) and (f) are SEM images of $\text{Mo}_2\text{TiAlC}_2$ and Mo_2TiC_2 , respectively. (g) and (h) are HRSTEM images of $\text{Mo}_2\text{TiAlC}_2$ and Mo_2TiC_2 , respectively. (i) Lower magnification TEM image of (f) showing the layered structure throughout the sample. (j) and (k) are SEM images of $\text{Mo}_2\text{Ti}_2\text{AlC}_3$ and $\text{Mo}_2\text{Ti}_2\text{C}_3$, respectively. HRSTEM images of (l) $\text{Mo}_2\text{Ti}_2\text{AlC}_3$ and (m) and (n) are $\text{Mo}_2\text{Ti}_2\text{C}_3$.

chemistry, precursor selection processing and template removal. With regards to the soft templating methods, most of the issues relate to choice of surfactant such as CTAB or cetylpyridinium bromide (CPBr) or even the use of long chain *N*-eicosane-*N,N*-dimethyl-*N*-(2-hydroxyethyl) ammonium bromide (EDMHEAB) and creating the surfactant assisted liquid-crystal mesophases while studying their stability to generate mesostructured non-oxide ceramics. Both approaches utilize exploiting a framework mesoporous structures of aluminosilicate, silica (SBA-15 or SBA-16) that serves as a template for conducting the polymerization, pyrolysis and other related chemical reactions as a structure directing agent (SDA) which result in the final product assuming the configuration and microstructure of the underlying template. The template is then removed leaving behind the final material assuming the morphology of the template akin to the topotactic mechanism well-known described earlier. Intrinsic porosity can in most cases be achieved by pyrolysis of the related polymers with removal of excess carbon, nitrogen and sulfur typically present in the polymer backbone contributing to the porosity. **Fig. 25** is an example of synthesis of ordered mesostructured BN or BCN from self-assembly and pyrolysis of a block copolymer of laboratory created polymer such as polynorbomene-*b*-polynorbornedecaborane (PNB-*b*-PDB) with microstructure that can be tailored by choice of a suitable organic solvent and the composition controlled by the pyrolysis atmosphere: nitrogen to give BCN and ammonia to yield BN, thus generating mesoporous ordered boron nitride (BN) or boron carbonitride (BCN). Another example in **Fig. 26** is that of mesoporous WS_2 generated by high temperature reductive sulfuration or sulfuration of phosphotungstic acid with H_2S and H_2 showing the orientation correlation between the resulting WS_2 crystal layers and the mesochannels afforded by the silica template of SBA-15 and KIT-6: the *c*-axis of the WS_2 layered crystals being always perpendicular to the original mesopore long direction as shown in the inset of **Fig. 26(a)**.

Summary

The above techniques describe the various approaches used to generate advanced ceramics over the period spanning almost three decades. These novel approaches not only enable generation of interesting systems for various applications but also demonstrate

Fig. 25 (Top) synthesis of ordered mesoporous BN or BCN from self-assembly and pyrolysis of block copolymer (PNB-*b*-PDB). (Bottom) SEM image and high magnification image (inset) of the resulting mesoporous BCN.

Fig. 26 TEM images (a), (b) and SAED pattern (inset of (a)) of mesoporous WS_2 synthesized by high temperature reductive sulfurization approach. The inset of (a) also shows the orientation correlation between the WS_2 crystal layers and the mesochannels of the silica template: the *c*-axis of the WS_2 layered crystals is always seen to be perpendicular to the length direction of the original mesopore of the silica template.

the ability of the process and the system to exhibit different morphologies depending on the approach adopted for a given system ranging from spherical particles to nanorods, fibers, whiskers, and platelets including aligned structures depending on the system and the process. The possibility of achieving new nanostructured materials with novel microstructures exhibiting remarkable properties has led to the identification of novel non-equilibrium techniques and template based approaches which enable the systems to be created in unique nanostructured morphologies that were never before possible under equilibrium conventional methods. The continuing advances in theory and fundamental aspects of materials processing will no doubt continue to lead to further advances in the synthesis of novel advanced ceramic materials. Thus the new millennium will continue to witness further advances in the area of synthesis of nanoscale and new materials under the materials genome initiative coupled with advanced computational tools including the fusion of machine learning algorithms data mining and various evolving artificial intelligence platforms which will enable not only identification of new and advanced systems but will also help identify the configuration and morphology needed to deliver the optimal and best performance. This will allow the experimentalists to continue to aspire to come up and invent newer techniques for realizing the potential of systems identified by theoretical calculations for a number of applications ranging from electronics, optics, electrochemical, magnetics, stem cells, organ engineering, and biomaterials to the growing field of tissue engineering.

Acknowledgment

The author would like to acknowledge NSF (CBET – Grant 0933141, CBET – Grant 0933153 and CBET – Grant 1511390) for support of this work. Acknowledgment is also due to the U.S. Department of Energy (DOE), Office of Basic Energy Science, Division of Materials Sciences and Engineering under Award DE-SC0001531 for supporting some of the work described here. In

addition, the author gratefully acknowledges the support of the Edward R. Weidlein Endowed Chair Professorship funds as well as the Center for Complex Engineered Multi-functional Materials (CCEMM) in the Swanson School of Engineering at the University of Pittsburgh for partial support that made this work possible.

Introduction

Aim of this chapter is to describe wet-chemical routes of both oxide and non-oxide ceramic particles. The main solution-based technologies are described, focusing on the process, providing some examples and highlighting both advantages and drawbacks in controlling the final particle features. For the manufacturing of advanced ceramics, in fact, primary particles with suitable physicochemical characteristics should be used, where these characteristics include the purity, the homogeneity, the density, the particle size, the particle size distribution, the shape and morphology, the specific surface area and the surface chemistry.

Although wet-chemical routes are effective in controlling the aforementioned characteristics, each synthesis is more suitable than the others in controlling some specific parameter, also considering the wide range of ceramic particles type nowadays required in ceramic processing, which include single-phase, multi-cationic, complex phases and composite powders, either in the oxide and non-oxide systems.

While single-phase ceramic particles with the desired characteristics are relatively easy to prepare, the synthesis of multi-cation or composite powders is more challenging. In fact, the conventional powder technologies for these types of powders requires three consecutive steps, namely mixing, solid-state reaction, and milling. The overall process can produce undesirable characteristics, which include phase and stoichiometric heterogeneities, poor control of size and morphology, significant particles aggregation. In many cases, to improve the characteristics of conventional powders, repeated calcination and milling steps are performed, with a consequent increased risk of pollution from the milling media. The limitations of the mixing-and-milling route drove the research towards the development of chemical synthesis methods for producing ceramic powders.

Wet-chemical syntheses include several technologies. The ones discussed in this chapter all use a liquid phase to solubilize one or more components in the process. In particular way, the routes described in this contribution are classified into three types, depending on where the chemical supersaturation (which produces the particle phase) takes place: (1) in the bulk liquid phase (includes sol-gel and precipitation); (2) between heterogeneous phases (includes solvothermal synthesis and molten salt synthesis); (3) in a droplet (includes microemulsions and spray syntheses).

Chemistry in the Bulk Liquid Phase

Sol-Gel Synthesis

Overview of the process

Sol-gel process can be described as the formation of an oxidic network through the polycondensation reaction of a molecular precursor in a liquid (Gonzalo-Juan and Riedel, 2016). This technique is suitable for both oxide and not-oxide ceramics, in the form of bulk materials, films, coatings, particles and fibers.

The term *sol* refers to a dispersion of colloidal particles in a liquid medium, where the stability of the colloids, at room temperature, is due to both Brownian motion and small particle size, which is usually less than 1 μm . As an alternative to *sol*, *solutions* can also be used, where the latter is thermodynamically stable, contrary to the former. The term *gel* refers to a three-dimensional network of a solid phase interwoven with an entrapped and immobilized continuous liquid phase.

The sol-gel process involves the preparation of a precursor mix (a *sol* or a solution), which transforms into a more solid-like material as a result of evaporation of the solvent, dehydration, and chemical cross-linking between the solid particles or dissolved precursors. The transformation of a *sol* or solution into ceramic material, via a gel-like intermediate, can be often accomplished at temperatures that are significantly lower than those necessary in “traditional” processing. This is because the precursors used are intermixed at a molecular level and can react through chemical pathways to form a network of chemical bonds that are characteristic of ceramic materials.

Precursors for the process can be either inorganic metal salts and metal alkoxides, $\text{M}(\text{OR})_n$. Alkoxide molecules exist as low molecular weight species, usually monomers or small oligomers, depending on the particular alkoxides used, the solvent, and other factors. The polymerization of these species occurs via hydrolysis of the M-OR species and polycondensation reactions involving the resulting M-OH group. Water acts as the “initiator” and is usually externally added. Water can also be generated in-situ by condensation reactions such as the formation of esters by the condensation of carboxylic acids and alcohols. Acids or bases are used as catalysts for these reactions.

Fig. 1 Main reactions, processes and products involved in the sol-gel synthesis route.

The (complete) reaction of metal alkoxides with water provides the hydrolysis reaction:

In this process, proper care must be taken in handling, packaging, and using metal alkoxides. Even traces of moisture are often sufficient to cause pre-hydrolysis and undesirable precipitation of hydroxides.

The synthesis proceeds through the following condensation reactions:

The products of condensation reactions may be alcohol, water, or both, depending on the alkoxide used. Thus M-O-M bonds can form during the condensation reactions that occur using either alkoxide or colloidal oxide precursors. As an example, the overall reaction to synthesize silica is shown in the following:

It should be specified that sol-gel is referred to as hydrolytic process when water, used as the solvent or generated in-situ during by the condensation reactions, is the oxygen donor. On the opposite, non-hydrolytic (i.e., non-aqueous) sol-gel occurs under organic solvents, where the precursors (alkoxides, acetylacetonates, etc.) react with oxygen donors (metal alkoxides, ethers, alcohols, acetates, aldehydes, ketones, etc.). While hydrolytic sol-gel allows the production of only metal oxide ceramic particles, in the case of non-aqueous process, both oxide and non-oxide ceramic particles (such as silicon carbonitride, $Si_xC_2N_y$, GaN, CdSe, CdTe) can be produced (Gonzalo-Juan and Riedel, 2016).

After the polycondensation reactions and the gel formation, a further critical step is the solvent removal. The most traditional process implies the evaporation of the solvent, which induces a capillary pressure and consequent shrinkage of the gel, which is referred to as *xerogel*. A second possibility implies the extraction of the solvent under supercritical conditions: in an autoclave, the removal of the solvent is carried out at pressure and temperature higher than the solvent critical point. Under these conditions, the lack of liquid-vapor interface impedes the formation of capillary pressure, and therefore drying occurs with little shrinkage. The product is named *aerogel*, and is normally characterized by a very high porosity in the nanometer scale and large surface area. Finally, the gel can be freeze dried, meaning that the pore liquid is frozen and then sublimed, producing a material named *cryogel*. In Fig. 1, a scheme of the sol-gel process is proposed, within the different dried products.

Advantages, issues, applications

The main advantage of this process lies in the low temperatures involved. In fact, through the polycondensation reactions shown in Eqs. (2) and (3), a network of metal-oxygen bonds is created at very low temperatures, typically lower than 100°C. Here, the choice of suitable precursors is one key, justifying the preferred choice of metal alkoxides and colloidal oxides as precursors. Other advantages include the high purity of the products and the ability to synthesize oxide ceramics in different product forms. The versatility of the process towards the development of different products (i.e., powders, thin films and coatings, fibers, bulk ceramics) is still depicted in Fig. 1.

Fig. 2 (a) Digital photos of the uncoated and sol-gel derived TiO_2 -coated SiC foams; (b) morphology of Nextel 720 fibers within a fiber-reinforced SiC composite; Microstructure of sol-gel-derived α -alumina ceramic fibers: (c) superfine-microstructure, dense alumina fiber after sintering with nucleating agent and (d) coarse-microstructure, porous alumina fiber after sintering with no nucleating agent. (a) Modified from Hao, D., Yang, Z., Jiang, C., Zhang, J., 2014. Synergistic photocatalytic effect of TiO_2 coatings and p-type semiconductive SiC foam supports for degradation of organic contaminant. *Applied Catalysis B: Environmental* 144, 196–202 with the permission of Elsevier under the license no. 4900191225167; (b) reprinted from (Chen *et al.*, 2005) with the permission of Elsevier under the license no. 4900730728115.

Among the disadvantages, it should be mentioned the high cost of the precursor alkoxides. As a second, important issue, the preparation of composites or multiphase ceramics is still a complex issue. To produce two phase materials, for instance, cross-condensation reactions should occur, i.e., reactions between species from two or more cations:

In principle, these reactions are possible, and solution containing different alkoxides could be used to construct a network of many cations. In practice, however, differential hydrolysis and polycondensation rates of different alkoxides pose a problem. Also, certain metals may be introduced in the form of other precursors that do not exhibit hydrolysis and polycondensation reactions. Different approaches including pre-hydrolysis of the more slowly reacting metal alkoxides as well as stabilization of highly reactive metal alkoxides by a molecular modification process have been developed to tackle this important problem (Phulé and Khairulla, 1990).

Commercial applications of sol-gel technology include the areas of optical fibers, refractory and reinforcing ceramic fibers, abrasive minerals, aerogels, coatings. An example of sol-gel derived TiO_2 coating on a SiC foam is depicted in Fig. 2(a) (Hao *et al.*, 2014). The first practicable sol-gel process for making high-quality silica optical fibers was reported by researchers at Lucent Technology (MacChesney *et al.*, 1999). More specifically, the sol-gel process is used for the production of silica tubes which serve as overcladding material of the optical fibers. Very high silica purity and dimensional control are the key requirements, which justify the choice of a colloidal sol-gel route. In fact, the high cost of the organometallic precursors and the large drying shrinkage make unfeasible the alkoxide route. As a precursor, largely available and low cost silica fume was used, and tetramethylammonium hydroxide was added to stabilize the suspension and decrease the viscosity. Then, addition of an ester (methyl formate) decreased the pH and induced gelation, which occurred within 10 min, allowing casting in a precision mold, demolding and drying. Purification was carried out at 1000°C in a chlorine-containing atmosphere to remove residual water and volatile organics. Finally, highly pure and transparent silica was obtained after sintering at $1500\text{--}1550^\circ\text{C}$. Optical fiber preforms are then fabricated by collapsing the tube over a vapor-deposited core rod, and high-quality optical fibers are then drawn from such optical fiber preforms.

Other examples of commercial applications of the sol-gel process include the development of the Nextel fibers by 3M Company. Nextel fibers are prepared by extruding, drying, and firing a concentrated sol containing a basic aluminum salt mixture

along with additives such as colloidal silica, organic polymers, and, in some cases, a boron oxide precursor. In general, the Nextel fibers are polycrystalline, transparent, and can be woven or braided for different engineering applications. Nextel 312 fibers based on a ceramic consisting of 62% Al_2O_3 , 14% B_2O_3 , and 24% SiO_2 , are processed using a colloidal sol-gel process. Nextel 720 is another grade of 3M fibers, composed by 85% Al_2O_3 and 15% SiO_2 , which gives rise to an alumina/mullite composite. (Tariq *et al.*, 2011). The morphology of this fiber, within a SiC-based composite, is depicted in Fig. 2(b). Nextel 610 fibers are high-modulus, α -alumina ceramic fibers having an exceedingly fine grain size (average grain size less than 2 μm). In the production of these fibers nucleating agents are used to reduce the sintering temperature, and therefore the average grain size. In Fig. 2(c), a sol-gel derived α -alumina fiber, characterized by a dense and ultrafine microstructure – due to sintering with nucleating agent – is depicted. In Fig. 2(d), the same fiber, but with a coarsened microstructure is shown: in this case, no nucleating agent has been added before sintering. Such sol-gel-derived ceramic fibers and materials find applications in insulation products, ceramic fiber-reinforced metal matrix composites and in reinforced ceramics and plastics.

Since 1970s, researchers at 3M Company began to develop sol-gel derived dense and tough ceramic materials, developing a number of abrasive minerals, including materials based on α -alumina/spinel mixtures, superfine-grained aluminas, and alumina/rare earth aluminates. The synthesis of these materials involves first forming a concentrated sol of boehmite (aluminum oxy-hydroxide) which is gelled either by raising the ionic strength of the sol or by heating. To form the ceramic abrasive grain, the boehmite gel is dried, crushed to size, calcined, and fired to full density.

In many familiar applications, sol-gel-derived products play an important role that is often not readily recognized. For example, precipitated silicas are used as a filler material in the manufacture of automobile tires. Other products such as paints and toothpastes also often make use of colloidal silica particles. Some of the other applications of sol-gel-derived products include antireflective coatings, abrasion resistant coatings for ophthalmic products such as eyeglasses and contact lenses, spin-on glasses for dielectric planarization, ferroelectric thin films, electrochromic coatings, and thin layers of transparent oxide conductors.

Precipitation

Overview of the process

Precipitation can be performed either under direct- and reverse-strike mode. In *direct strike precipitation*, the most commonly employed method, a precipitating agent or solution is dropwise added to a metal salts solution. Upon addition of the precipitant, the salts solution pH increases, leading to hydroxides precipitation. On the opposite, in *reverse strike precipitation*, a soluble salts solution is slowly added to a solution containing the precipitating agent, inducing a progressive pH decrease of the precipitating solution. When two or more chemical species have to be simultaneously precipitated (process referred to as *co-precipitation*) the salts solution and an extra-precipitation solution are added at the same time. In such a way, the pH is kept to a constant value, corresponding to the hydroxide formation of both species (Palmero *et al.*, 2005; Palermo and Traverso, 2014), thus assuring the simultaneous and quantitative precipitation of both. As respect to direct strike precipitation, this last route allows a higher homogeneity of distribution of the different elements, providing lower crystallization temperature of the multi-cationic oxide material. Precipitation is a suitable route for preparing both oxide and non-oxide ceramic particles. In the case of oxide ceramics, the precipitation of lanthanum-modified lead zirconate titanate is shortly described here: lead and lanthanum nitrates, zirconium oxychloride, titanium tetrachloride, and hydrogen peroxide are used as precursors, and dissolved in water at 40°C. Upon addition of ammonium hydroxide till the achievement of a pH of 9, the precipitation of mixed hydroxides occurred. After washing, drying and calcination at 650°C, the complex oxide formed. Concerning non-oxide ceramic particles, silicon nitride was produced starting from silicon chloride (SiCl_4) which was precipitated under ammonia addition, providing silicon diimide $[(-\text{Si}(\text{NH})_2)_x]$, which was then converted to Si_3N_4 by pyrolysis at 1200–1700°C.

Direct precipitation method can be assisted by the addition of a non-solvent. First, an aqueous solution is prepared and then precipitation is induced by dilution with a hydrophilic non-solvent. Soluble salts employed include sulfates, citrates, and nitrates, while alcohol (ethanol, isopropanol, etc.) or acetone are typically employed as the non-solvent. Proper choice of the salt concentration, solution environment (pH, addition of complexing agents) and non-solvent is essential to achieve the proper stoichiometry and satisfactory homogeneity. Materials such as barium titanate, lead zirconate, magnesium aluminate, and manganese ferrites can be prepared.

The conventional precipitation processes, where the precipitant solution is added to the reaction medium, often produces localized concentration effects. To overcome such an issue, *precipitation from homogeneous solutions* can be performed, where the precipitant is generated over a long period of time and uniformly throughout the entire reaction region. Here, the level of supersaturation remains low, providing the precipitation of compact crystals instead of coagulated colloids, completely avoiding concentration gradients. In order to control particle size, size distribution and morphology, special attention must be given to concentration, pH, heating rate, temperature, corresponding anion of the soluble metal salt, choice of precipitating reaction, and aging conditions. The most commonly used precipitation from homogeneous solution technique uses a soluble salt co-dissolved with a precursor that decomposes upon heating, releasing an anion that quantitatively precipitates the dissolved cation. As an example, the synthesis of zinc oxalate dihydrate is here reported, starting from an aqueous solution of oxalic acid-zinc nitrate, via anion release:

The release of the oxalate anion is being regulated by the rate of diethyl oxalate decomposition in a solution of dissociated Zn^{2+} to precipitate $\text{ZnC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, as shown below:

This technique can also be used to prepare multicomponent powders with controlled stoichiometry and phase homogeneity, such as strontium-titanium hydrous oxides and yttria-doped zirconium hydrous oxide. In order to obtain a phase-homogeneous powder with the intended cation stoichiometry, careful attention must be paid to the preparation of the homogeneous solution and the types of multicomponent complexes that form. Finally, the feasibility to prepare not-oxide powders was demonstrated as well: submicron diborides of titanium, zirconium, and hafnium are prepared by refluxing metal borohydrides in xylene at 140°C:

Silicon and titanium carbides were produced from chlorides, by dehalogenation and carburization in n-heptane at 130°C, as shown in the following reaction:

Advantages, issues, applications

Precipitation and co-precipitation offer advantages in terms of fine particles size, controlled stoichiometry and purity of the final powders. As in other wet-chemical synthesis methods, agglomeration of the particles is one of the major issues. In addition, the common ion effect can induce heterogeneities in the system. This could happen in multi-component precursor solutions, when the anion of a soluble salt makes insoluble the cation of another salt. Such a heterogeneous precursor system is unlikely to produce a physically and chemically uniform powder. To avoid this issue, the solubility of all salts included in the system must be carefully taken into account.

A further undesirable effect relates to the anionic by-products (e.g., chlorides and sulfates) which can be co-precipitated within the primary products. These impurities can be incorporated into the particles as lattice defects or can adsorb onto powder surfaces. In addition, soluble species in solution can become occluded within particle agglomerates. Proper choice of the soluble anions in solution is important in order to minimize the above problems. Anions which decompose at low temperatures are preferred, since they can be eliminated from the powder during calcination. For examples, nitrates should be preferred to chlorides, due to the lower decomposition temperature of the related by-products.

One of the most important industrial example of precipitated powder is $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ (gibbsite), which is precipitated from a sodium aluminate solution (Bayer process). Subsequent calcination produces transition or α -alumina, which finds several commercial applications for abrasive materials, fire-retardants, adsorbents, catalysts, ceramics and fillers for polymeric composites (Denigres Filho *et al.*, 2016). A second example is provided by the precipitation of $\text{Mg}(\text{OH})_2$ that form a brine solution, which is again calcined to give the 'dead burnt' magnesia (Ring, 1996), the main raw material for basic refractory products. As an example, companies like Martin Marietta Magnesia Specialties, LLC (US) and Terna Mag (Greece) supply these kinds of product.

Co-precipitated yttrium aluminum garnet (YAG) powders can be used for the production of polycrystalline sintered transparent ceramics. To achieve optical transparency, the starting powders should satisfy some strict requirements, consisting in extreme purity, controlled stoichiometry, ultrafine particle size, and narrow particle size distribution, allowing to produce fully dense ceramics. As an example, a transmission electron microscopy micrograph of a co-precipitated YAG powder (after calcination at 1350°C) is depicted in Fig. 3 (left), where the nanometric size of the primary particles can be observed (Palmero *et al.*, 2005). Moreover, the formation of a well-crystallized and pure YAG phase was confirmed by comparing the experimental interplanar distances (d_{hkl} values) measured from the electron diffraction pattern with the nominal ones, as reported in the Table at the center of Fig. 3. Such a fine, homogenous, pure powder was suitable for the production of transparent sintered ceramic, as depicted in Fig. 3 (right) (Spina *et al.*, 2012; Palmero *et al.*, 2013). Polycrystalline transparent ceramics can be used as high-energy laser windows: for example, a 1.46 kW Nd: YAG laser has been demonstrated by Konoshima Chemical Co. in Japan, while transparent ceramics (YAG and yttria) are currently commercialized by CoorsTek (see "Relevant Website section").

Chemistry Between Heterogeneous Phases

Solvothermal Synthesis

Overview of the process

Starting from the '70s, the direct precipitation of crystalline oxide structures become feasible thanks to the introduction of the hydrothermal syntheses. Solutions, gels and suspensions are used to precipitate anhydrous oxides, being the reactants placed in closed vessels and processed under high pressure and temperature conditions, allowing solubilization reactions which are not allowed under ordinary temperature and pressure ($< 100^\circ\text{C}$, < 1 atm).

More precisely, solvothermal synthesis can be carried out either under mild or extreme conditions. In the former case, reactions are carried out below $\sim 300^\circ\text{C}$, due to the fact that the ionic products have typical values in the range 250–300°C (Hayashi and Hakuta, 2010), avoiding reaching the critical water pressure and temperature (22.1 MPa and 374°C, respectively). In the second case, such values are overcome, causing a significant change of some physical properties such as dielectric constant and solubility, affecting reaction rate and providing favorable conditions for particle formation (Hayashi and Hakuta, 2010).

Even though mild conditions ($T < 350^\circ\text{C}$ and $P < 50$ MPa) are preferred, in order to lower the process cost and extend the durability of the reactions vessels (Suchanek and Riman, 2006), supercritical conditions (up to $T \sim 1000^\circ\text{C}$ and $P \sim 500$ MPa)

Fig. 3 (left): Transmission electron microscopy micrograph of co-precipitated yttrium aluminum garnet (YAG), after calcination at 1350°C. Inset to the figure, the electron diffraction pattern to derive the interplanar distances, reported in the table (center); (right): digital photo of polycrystalline sintered YAG, showing high optical transparency.

(Roy, 1994) allows faster reactions (reaction rate $> 10^3$ times compared to conventional hydrothermal conditions) and higher degree of crystallinity in the products.

Mild hydrothermal synthesis can proceed either by in situ transformation or dissolution/re-precipitation mechanisms. In the former case, the dispersed particles undergo a polymorphic or chemical phase transformation. For example, titanium hydrous oxide can be chemically transformed into polycrystalline anhydrous anatase phase by refluxing the powder for 12 h in an ammonium hydroxide-water solution, at pH 10, atmospheric pressure and temperature of 100°C. In the case of dissolution-reprecipitation mechanism, the dispersed particles dissolve into solution, supersaturate the solution phase and then reprecipitate. In most cases, the solubility needs to be improved by proper solubilizing components. For example, a hydrothermal reaction at low pH (< 3.5) dissolves the zirconium hydrous oxide precursor in soluble species, that subsequently reprecipitates the zirconium oxide.

Hydrothermal synthesis has been successfully used for the preparation of a number of ceramic particles, including single-phase, complex oxides as well as non-oxide ceramics (Suchanek and Riman, 2006). Among the single phases, numerous studies relate to the hydrothermal preparation of silica, alumina, zirconia (stabilized by calcia, yttria, scandia, ceria, etc.) (Sato *et al.*, 2015; Kim *et al.*, 2012; Rizzuti *et al.*, 2009), titania, zinc and iron oxide. A number of complex oxides were synthesized as well: perovskites, such as titanates ($ATiO_3$, with $A = Ba, Ca, Sr, Pb$, etc.) (Walton, 2020) zirconates ($BZrO_3$, $B = Ba, Ca, Sr$) and their mixed oxides like $Pb(Ti_{1-x}Zr_x)O_3$ (PZT); niobates (such as $KNbO_3$ and $LiNbO_3$); cobalt and nickel ferrites (such as $CoFe_2O_4$ and $NiFe_2O_4$) (Zalite *et al.*, 2015; Bućko and Haberko, 2007); apatites; zeolites, etc. In addition, nanocomposite powders, such as alumina-hydroxyapatite (Sivaperumal *et al.*, 2017), alumina-yttria stabilized zirconia (Geuzens *et al.*, 2008), magnetite-hydroxyapatite (Murakami *et al.*, 2008), titania-hydroxyapatite and titania-silica (Suchanek and Riman, 2006) as well as core-shell structures particles (CdS/ZnO , $CoAl_2O_4/ZnAl_2O_4$) (Suchanek and Riman, 2006) have been also successfully prepared. The process also allows the preparation of non-oxides ceramics, such as nickel or cobalt selenides, lead or cadmium tellurides, cobalt, tin, or molybdenum sulfides, vanadium nitrides, rare-earth fluorides, (cubic BN, hexagonal BN), arsenides ($InAs$, $GaAs$), etc (Suchanek and Riman, 2006; Huang *et al.*, 2014; Wang *et al.*, 2006).

Crystalline products can be in a variety of forms, such as equiaxed (for example cubes, spherical), elongated (fibers, whiskers, nanorods, nanotubes), plates, nanoribbons, nanobelts, etc. Fig. 4 depicts the transmission electron microscope images of different ceramic particles produced under supercritical water conditions (Hayashi and Hakuta, 2010), showing the effectiveness of the method in producing different powder morphologies.

Advantages, issues, applications

Compared to conventional wet-chemical routes, hydrothermal synthesis offers numerous and significant advantages. First, all types of ceramic can be synthesized, such as powders and fibers, single crystals and polycrystalline ceramics, bulk materials and coatings. Then, the precipitation of already crystallized phases is a unique feature, while the control of particle size, shape and agglomeration degree is improved as respect to traditional processes. The synthesis of metastable compounds is possible as well, which is not feasible under the conventional high temperatures processing methods. A poorly agglomerated powder, characterized

(a) $\text{Y}_x\text{Zr}_{1-x}\text{O}_2$, (b) $\text{K}_2\text{Ti}_6\text{O}_{13}$, (c) BaTiO_3 , (d) $\text{Ca}_{0.7}\text{Sr}_{0.3}\text{Ti}_{0.9}\text{Fe}_{0.1}\text{O}_3$. Reproduced from Hayashi, H., Hakuta, Y., 2010. Hydrothermal synthesis of metal oxide nanoparticles in supercritical water. *Materials* 3, 3794–3817, under the Creative Commons Attribution License.

by a narrow particle size distribution leads to higher fired densities and more microstructural homogeneity, which leads to more controlled final properties. Finally, in spite the application of temperature and pressure during synthesis, the following steps of calcination, mixing and milling are minimized, and therefore the whole process is a less time- and energy-consuming method respect to other wet synthesis technologies.

Only few disadvantages characterize the hydrothermal synthesis, such as the safety issues during the reaction process and the high cost of the autoclaves.

Starting from the 20th century, hydrothermal synthesis was clearly identified as an important technology for materials synthesis, predominantly in the fields of hydrometallurgy and single crystal growth. However, the severe (supercritical) reaction conditions required for growing single crystals have discouraged extensive research and commercialization for many materials. Currently, single crystals of α -quartz for frequency control and optical applications, ZnO for UV- and blue light-emitting devices, and KTiOPO_4 for nonlinear optical applications, are commercially available (Suchanek and Riman, 2006). In recent years, the commercial interest in solvothermal synthesis increased, and specifically in the field of primary ceramic particles, which can be processed under mild hydrothermal conditions (Suchanek and Riman, 2006). The widely used Bayer process uses hydrothermal methods to dissolve bauxite and subsequently precipitate aluminum hydroxide, which is later heat-treated at high temperature to crystallize as α -alumina. Sawyer Technical Materials, LLC recently developed hydrothermal production of high-purity α - Al_2O_3 particles, and powders characterized by different size and morphologies (equiaxed, needles, nano-sheets) are currently available on the market (see “Relevant Websites section”). The production of perovskite-based dielectrics and zirconia-based structural ceramics is a promising growth area for hydrothermal methods. Corporations such as Cabot Corporation, Sakai Chemical Company, Murata Industries, Ferro Corporation and others have established commercial hydrothermal production processes for making dielectric ceramic powder compositions for capacitors.

Molten Salt Synthesis

Overview of the process

Ceramic powders are solubilized into molten inorganic salts, which are used as high-temperature solvents, mimicking the crystal nucleation and growth processes which typically occur in conventional solvents. The procedure implies (1) the mixing of the reactants with a salt; (2) their heating above the salt melting temperature; (3) the dissolution of the reactants, their reaction and

Fig. 5 Scheme of the salt melt synthesis.

formation of the product that precipitate from the solution through nucleation and growth processes; finally, (4) the cooling down and final washing to remove the residual salt. A scheme of the process, showing the main above steps, is depicted in Fig. 5.

The product is formed through two stages. The former is the reaction, where the constituents (typically single-oxide phases) dissolve in the molten liquid and form the product. Here, under high saturation degree, two conditions can occur: (1) solution-precipitation, where both constituents dissolve in the molten liquid and the product is formed by precipitation; (2) solution-diffusion, where just one constituent dissolves, then diffuses in the melt and react with the second solid constituent, providing the product. In these stages, the particles shape is similar to that of one of the reactive. Then, upon further heating, the growth stage of the product starts, following an Ostwald ripening mechanism which determines the size distribution of the product particles. Here, the particle shape approaches the equilibrium one. It should be mentioned that the solubility of metal oxide in molten salts varies from less than 1×10^{-10} mol fraction to more than 1×10^{-3} mol fraction (Gonzalo-Juan and Riedel, 2016): the difference from typical solvent-based synthesis, where the solubilization of the reactants is almost complete and the precipitation occurs from homogeneous solution, is evident.

Molten salt synthesis has been successfully used to prepare both single crystals and polycrystalline ceramic powders. In the case of single crystals, the cooling conditions have to be controlled thus to generate a limited number of nuclei; on the opposite, for powders, an elevated nuclei number is required, which also affects the particles final grain size, that can range from a few tens nanometer to few tens micrometers.

The presence of molten salts play some key roles in this process, since they increase the reaction rate, decrease the reaction temperature compared to solid state synthesis (due to the increased mobility of the reactive phases), control the particle size, shape and agglomeration degree of the final product. Salts are required to be stable under the used conditions, readily available, inexpensive, and they have to be easily washed away with water (Kimura, 2011). Typical salts used in molten salt synthesis are chlorides and sulfates, while in many cases eutectic mixtures of salts are used, in order to decrease the liquid formation temperature.

As an example, the synthesis of lead zirconate titanate is here reported, where TiO_2 , ZrO_2 , PbO are mixed together in an aqueous slurry. A KCl-NaCl molten salt eutectic is mixed into the slurry, causing the system to gel. Upon drying, the mixture is heated at $\sim 1000^\circ\text{C}$ to form the lead zirconate titanate, which is subsequently washed, to eliminate both molten salts and any excess unreacted ions. Sodium iron titanate has been also successfully synthesized by molten salt procedure (Zhang *et al.*, 2019). As raw materials, Na_2CO_3 and FeTiO_3 were used, while NaCl, at the optimal molar ratio α of 4 (where α = moles of the molten salt respect to the moles of the raw materials) was added to generate the molten liquid medium at temperatures between 600 and 1000°C . Under these conditions, needle-like NaFeTiO_4 particles were obtained, while when extra Fe_2O_3 powder was added as raw material, a different morphology and composition was produced, yielding $\text{Na}_{0.75}\text{Fe}_{0.75}\text{Ti}_{0.25}\text{O}_2$ platelets, as shown in Fig. 6.

In some cases, the salt can participate to the reaction, as in the following example, where the salt cation directly contributes to the formation of the final product:

Here, the high volatility of TiCl_4 favors the elimination of the synthesis by-product.

Advantages, issues, applications

The main advantages of the molten salt synthesis are the simplicity, the versatility and the cost-effectiveness. In addition, compared to the traditional solid state reaction, where sintering implies neck formation and thus particles agglomeration, here the molten salt covers the surfaces of the reactive particles and prevents the formation of necks between the produced compounds, limiting the agglomeration degree.

In addition, this synthesis route is particularly suitable for covalent-bond based ceramic particles, such as borides, carbide and nitrides. For such non-oxide ceramics, mild synthetic conditions yield amorphous or poorly crystallized materials, since the high

Fig. 6 SEM images of (a1, a2) NaFeTiO_4 needles (formed at $\alpha = 4$, $T = 900^\circ\text{C}$, and $t = 4$ h), and (b1, b2) $\text{Na}_{0.75}\text{Fe}_{0.75}\text{Ti}_{0.25}\text{O}_2$ platelets (formed at $\alpha = 4$, $T = 1000^\circ\text{C}$, and $t = 4$ h). Reprinted from Zhang, H., Li, M., Zhou, Z., Shen, L., Bao, N., 2019. Microstructure and morphology control of potassium magnesium titanates and sodium iron titanates by molten salt synthesis. *Materials* 12, 1577, under the Creative Commons Attribution License.

temperatures required to crystallize these powders normally exceed the operational temperatures allowed with organic solvents. This drawback can be overcome by the molten salt synthesis, thanks to the wide operational temperature (from 100 to 1000°C), the high mass transfer and high thermal conductivity of the system, which make feasible the synthesis of crystallized not-oxide ceramics (Gonzalo-Juan and Riedel, 2016).

The most important disadvantage relies to the numerous washing steps necessary to eliminate the residual salts, especially in the case they adsorb on the particle surface, and of the other synthesis by-products.

During the last 15 years, the interest towards molten salt synthesis significantly increased, especially for the preparation of multi-cationic materials such as ferroelectric and ferromagnetic ceramics, materials for Li-ion batteries (Santhanam and Rambabu, 2010), semiconductors (Huang *et al.*, 2010), phosphors (Yan and Lei, 2010), and photocatalysts (Arney *et al.*, 2008), especially when nano-sized materials are required (Mao *et al.*, 2007). In spite salt melts have been widely used as solvent, even at the industrial level, due to their low toxicity, low cost, low vapor pressure and large availability, no ceramic products based on molten salt synthesis (to the best of the authors' knowledge) are currently commercially available.

Chemistry in a Droplet

In this approach, the synthesis is confined within a solvent droplet, which controls the physical characteristics of the resulting powder and limits chemical segregation to the droplet scale. The syntheses included in this category involve the use of either liquid phase system (such as emulsions or microemulsions) or liquid-gas phase systems (such as aerosols and spray pyrolysis).

Emulsion and Microemulsion Synthesis

Overview of the process

An emulsion is a mixture of two immiscible liquids in which one liquid is dispersed into the other with the aid of a surfactant. A single or a mixture of surfactants stabilizes the emulsion by reducing interfacial tension, reinforcing the interfacial film, preventing coalescence of the droplets.

Surfactants as amphiphilic molecules made by hydrophilic head and a hydrophobic tail, which tend to adsorb at the water/organic phase interface and decrease their surface energy. This generates a dispersed phase confined in nanometer regimes, in which the synthesis of nanoparticles can be carried out (Sadat-Shojai *et al.*, 2013). Three types of emulsions can be prepared: water-in-oil, oil-in-water and water-in-oil-in-water double emulsion (Sadat-Shojai *et al.*, 2013), being the former one the mostly used for

Fig. 7 Fusion process of the reverse micelles containing different ions to form hydroxyapatite nanoparticles of spherical morphology (condition I) or rod-like morphology (condition II). Reprinted from Sadat-Shojai, M., Khorasani, M.-T., Dinpanah-Khoshdargi, E., Jamshidi, A., 2013. Synthesis methods for nanosized hydroxyapatite with diverse structures. *Acta Biomaterialia* 9, 7591–7621, with the permission of Elsevier under the license no. 4901260452701.

the synthesis of single-phase oxides (TiO_2 , ZrO_2 , SiO_2 , GeO_2 and Fe_2O_3), multicomponent oxides (such as MnFe_2O_4 and other ferrite materials) (Malik *et al.*, 2012) and non-oxide ceramics such as the carbides of thorium or uranium.

Water-in-oil emulsion consists on the preparation of a stable colloidal sol, emulsified in an oil medium to form spherical droplets. Then, two methods can be used to induce the gelation of the droplets. In one case, dehydration or evaporation of the liquid is used. In the case of dehydration, an organic phase such as a long-chain alcohol (2-ethylhexanol) is used to concentrate the sol by dehydrating the droplets, through flocculation of the sol (with possible precipitation reaction) inside the droplets. In the second case, gel can be formed upon pH variation inside the sol, for instance by adding urea which decomposes and releases ammonia in the aqueous phase during heating of the emulsion.

Emulsions typically show a milky appearance. They are kinetically stable but thermodynamically unstable, and therefore tend to separate into the constituent phases, causing the merging of the droplets and the separation of the second liquid phase.

Microemulsions allow to overcome this drawback, since they are stable by a thermodynamic point of view. Here, droplets with size lower than $0.15\ \mu\text{m}$ make the emulsion transparent, while for sizes larger than $1\ \mu\text{m}$, the appearance is turbid. In principle, the smaller the droplet size, the smaller the synthesized particles. Mixing conditions, surfactant types and concentration are the keys to control the size of the droplet.

Water-in-oil microemulsion are also known as reverse micelles, characterized by the ability to solubilize both hydrophilic and hydrophobic species. Even though the mechanism of nanoparticles synthesis is not completely understood, it seems to proceed in the following way: when reactants are included in a microemulsion and mixed together, intramicellar collisions promote the reactants exchanges, and consequently the occurrence of precipitation reactions, followed by nucleation and growth, resulting in the formation of the final nanoparticles surrounded by water and/or stabilized by the surfactants.

An example of multi-cationic ceramic phase produced by the microemulsion technique is provided by the synthesis of hydroxyapatite (Sadat-Shojai *et al.*, 2013). Specifically, the synthesis is carried out in a water-in-oil system, where a transparent microemulsion is made of reverse micelles dispersed in a continuous oil phase. Each micelle contains a droplet of solution in which the first precursor (e.g., calcium ions) is solubilized. Upon the addition of the second microemulsion, containing the other reagent (phosphate ions), collision and fusion between the reverse micelles occur, allowing the reaction between Ca^{2+} and PO_4^{3-} ions, followed by nucleation and growth of the hydroxyapatite crystals, as illustrated in Fig. 6. Considering that each reverse micelle acts as a nano- or micro-reactor, the same micelles also play a role as a templating agent, affecting the morphology and the size of the hydroxyapatite particles. A further key role in affecting particle size, morphology and crystallinity of the final particles is played by the surfactants, where the above features can be tuned by adjusting the electrostatic interaction between the ionic surfactants and oppositely charged groups on the hydroxyapatite surface. Therefore, by changing surfactant type, the electrostatic interactions change, and thus the particle features, which can move from spherical to rod-like, as schematically shown in Fig. 7.

Advantages, issues, applications

The main advantage of the microemulsion technique lies in the possibility to synthesize nanosized particles, where the droplets/micelles act as a template to tune the size and the morphology of the final particles, and the surfactant prevent their agglomeration (Sadat-Shojai *et al.*, 2013).

However, the formation of microemulsions generally requires large amounts of surfactants and/or co-surfactants, which are generally irritating when used at high concentrations (Gupta *et al.*, 2013). In addition, the microemulsion stability is affected by temperature, pH and other external factors.

Fig. 8 TEM images of the as-synthesized titania powders, at different hydrolysis water: titania precursor molar ratio: (a–b) $[\text{H}_2\text{O}]:[\text{Ti}] = 2$; (c) $[\text{H}_2\text{O}]:[\text{Ti}] = 4$. Reprinted from Ahonen, P.P., Tapper, U., Kauppinen, E.I., Joubert, J.-C., Deschanvres, J.-L., 2001. Aerosol synthesis of Ti–O powders via in-droplet hydrolysis of titanium alkoxide. *Materials Science and Engineering A* 315, 113–121 with the permission of Elsevier under the license no. 4905940125317.

As mentioned before, this synthesis route has been successfully used to prepare single-phase and multi-cation oxide, non-oxides, nanowires, nanocomposite ceramics. Concerning the applications, magnetic ceramic particles are successfully synthesized by the microemulsion technique (Wang *et al.*, 1997; Malik *et al.*, 2012) even though not yet at a marketable level. New applications arise from the development of 3D printing technologies for ceramic materials, namely concerning ceramic pigments (Chang *et al.*, 2018). A suitable ink for 3D printing should be prepared by fine powders and pigments, with size smaller than 1/100 that of the nozzle, to avoid clogging. Microemulsion is able to provide nanoparticles with size in the range ~ 0.2 – $1.0 \mu\text{m}$, thus meeting the demands of ink-jet printing. In addition, microemulsions can incorporate both hydrophilic and lipophilic species (like therapeutic agents and drugs) with application in medicine (Malik *et al.*, 2012).

Spray-Based Syntheses

Overview of the process

Aerosols or sprays are liquids dispersed in the gas phase. As with microemulsions (see section “Emulsion and Microemulsion Synthesis”), the droplet size directly affects the particle size, while droplet dimension is determined the precursor types and the method of aerosol generation.

Aerosols can be generated either by vapor condensation and mechanical condensation. Vapor condensation has been used primarily in low-temperature reactions, where the precursors contained in the droplets react with the species in the vapor phase, to form the particles, which have normally submicron size. For instance, titania and alumina ultrafine powders ($\sim 0.2 \mu\text{m}$), characterized by narrow size distribution, can be precipitated from monodisperse $0.4 \mu\text{m}$ aerosols of alkoxides (such as $\text{Ti}(\text{OR})_4$ and $\text{Al}(\text{O-sec-Bu})_3$) or metal tetrachlorides (such as SiCl_4 and TiCl_4) by seeding the vapor phase with silver chloride and subsequently hydrolyzing the droplets with water vapor at temperatures higher than 0°C , while the completion of the hydrolysis reactions occurred at aerosol temperature $\geq 100^\circ\text{C}$. The same route was used to prepare TiO_2 - SiO_2 composite powders, by diffusing SiCl_4 vapor into monodisperse $\text{Ti}(\text{OEt})_4$ droplets and subsequently hydrolyzing the multicomponent droplet. Here the major issue is the chlorine contamination, which could affect the following ceramic processing. A modified method was employed by Ahonen *et al.* (2001) to produce TiO_2 nanoparticles, where in-drop hydrolysis is carried out. $\text{Ti}(\text{OBu})_4$, hydrolysis water, and acetic acid were added to ethanol, and the solution was atomized. The spray was transferred to a tubular flow reactor (operating at 200°C , under N_2 /air atmosphere, at ordinary pressure): upon alcohol evaporation, polycondensation reactions and formation of titania particles occurred. As-synthesized particles were amorphous, and characterized by spherical morphology of few microns in size, as shown in Fig. 8. Crystallization of the anatase phase and rutile phase occurred at temperatures higher than 500 and 900°C , respectively.

The second route implies the mechanical condensation, where sols are sprayed into immiscible liquids, to form “gel-microspheres”, by a subsequent dehydration or pH change. An ultrasonic spray atomizer has been used to react aqueous zirconium nitrate with ammonia gas to precipitate a hydrous oxide. Electrostatic aerosols of aqueous solutions of zirconium acetate and

polyethylene oxide yielded 0.1–5.0 μm diameter acetate particles, which were subsequently calcined at 1100°C to form zirconia. In this system, varying concentrations of polyethylene oxide (<0.06 wt%) served as a means to control the particle size. Salts can be spray-dried as well; however, significantly larger particle sizes result. Iron oxides spray dried as various salts typically have particle sizes of 3–20 μm . Recently, the spray drying technique was used to develop alumina and zirconia-based nanocomposite powders (Palmero *et al.*, 2011; Palermo and Esnouf, 2011; Palermo *et al.*, 2014). Within this approach, a commercial and well dispersed alumina or zirconia powder is mixed with an aqueous salts solution, being the salts the precursors of the second phases. During atomization, instantaneous water evaporation occurs, thus to induce the quick and homogeneous precipitation of the salts on the particles surface, thus avoiding segregation phenomena which can occur during conventional drying procedure. During subsequent calcination, salts decomposition and reaction provide the formation of the desired second-phases. As compared to the traditional mixing and milling procedure, this process allows an optimal distribution of the second-phases within the composites, as well as a careful control of particle size, morphology, and composition of all the phases. The procedure applies to both reactive and not-reactive systems; in the former case, the salts react with the matrix material to produce the second-phase, as in the case of yttrium-doped alumina to produce $\text{Al}_2\text{O}_3\text{-Y}_3\text{Al}_5\text{O}_{12}$ composites; in the second-one, the salts just crystalize on the surface of the matrix material, as in the case of zirconium-doped alumina, to provide $\text{Al}_2\text{O}_3\text{-ZrO}_2$ composites.

Ceramic powders have been prepared by freeze drying, in which multicomponent liquid solutions are sprayed into a cold liquid to freeze the droplets which are then separated from the liquid and subsequently sublimed. Spherical alumina, magnesium oxide, and spinel powders with submillimeter particle sizes have been prepared from calcined sulfate salts by pneumatically spraying aluminum sulfate solutions into hexane solutions chilled with a dry ice-acetone bath.

Powders can also be precipitated in spray droplets by solvent replacement. This technique involves the addition of an aerosol of an aqueous solution of metal salts to a non-solvent that solubilizes water but not the dissolved salts.

In spray pyrolysis, liquid droplets are sprayed into a reactor that has a low-temperature chamber for precipitating salts and a high-temperature chamber for subsequent pyrolysis. Powders range from micrometer-sized shell-like aggregates to narrow size distribution submicron solid spheres. A broad range of oxide, non-oxide, and composite powders (e.g., WC/Co) are prepared using this approach. The problems inherent in spray pyrolysis are magnified due to the fact that reactor and precursor systems must incorporate the ideal attributes of both spray-drying and calcination processes. During drying, the kinetics of both solvent evaporation and salt precipitation propagating inwards from the surface of the droplet should be optimized while maintaining the spherical morphology. During pyrolysis, attention must be paid to the large amounts of volatile products that are associated with rate-limiting processes such as heat transfer, diffusion through a product layer, and crust formation. In addition, in each case it must be determined whether or not spray pyrolysis is a liquid-gas phase reaction or a vapor-phase process using a liquid precursor. If the latter process is occurring, particle size will not be controlled by droplet size.

Advantages, issues, applications

Aerosol synthesis, and particularly spray pyrolysis, offers several advantages, being the main one the high purity of the produced powder. Moreover, spray pyrolysis allows producing particles with a narrow size distribution and homogeneous composition, due to the reaction being confined to the droplet dimension. In addition, each droplet contains precursors in the correct amount, making stoichiometry well controlled in the final product. A further key of spray synthesis is the relative simplicity of the process, which allows easy scale-up to pre-industrial or industrial scale.

The main challenges for spray-based synthesis relate to the stoichiometric control, the difficulty arising from the different solubility of the precursors. This can lead to segregation phenomena, which is – however- limited to the droplet dimension. In addition, the droplet output from the spray source significantly affects the features of the products, being larger and less homogeneous particles those generated at higher atomizer output rate. A further issue is related to the formation of crashed or hallow particles, which is undesirable especially for ready-to-press powder production. More in general, the morphology control of the synthesized powders is still a challenge.

Summary

Advanced ceramics are designed and developed to satisfy a number of functional and mechanical properties, for applications which spread from structural, to biomedical, environmental, electronic, optical, thermal, and magnetic areas. To achieve the expected performance, a key role is played by the starting ceramics particles. For instance, the starting particle size, the size distribution, the agglomeration degree, the shape and the specific surface area play an important role on the compact sinterability, and thus on the final density, microstructure and physical-mechanical properties. At the same time, particle size, morphology, aspect ratio, chemical surface are important features to control the electrical or magnetic properties. As respect to traditional preparation routes, were precursors are typically submitted to long and repeated mixing, milling and calcination steps, with disadvantages related to lack of homogeneity, purity, compositional and morphological control, current wet-chemical routes offer many alternative approaches for preparing powders with ideal or near-ideal characteristics. This contribution explores some of these wet-preparation routes, with the aim of highlighting the potential in achieving the desired physical and chemical characteristics, the application field and – in some cases – the commercial availability of the powders or related ceramic products, but also the main issues. Final aim of this contribution is not only to revise the main synthesis routes belonging to the wide ‘wet-chemical route’ class, but also to provide readers some guidelines to choice the most appropriate technology, and to scientifically approach them.

Self-Propagating High-Temperature Synthesis

Jerzy Lis, AGH University of Science and Technology, Kraków, Poland

© 2021 Elsevier Inc. All rights reserved.

Introduction

The material presented in this chapter is assumed to be a basic lecture and it is addressed to those interested in materials and their technologies but not familiar with the SHS technique, especially for high school and university students as well as technologists working in industry. The text was prepared on the basis of the author's lectures for students of materials engineering, chemical technology and ceramics at the Faculty of Materials Science and Ceramics, AGH University of Science and Technology in Krakow, Poland. An advanced reader can find full information about SHS in numerous monographic studies, especially recently published "*Concise Encyclopedia of Self-Propagating High-Temperature Synthesis; History, Theory, technology and Products*" edited by Borovinskaya I.P., Gromov A.G., Levashov E.A., Maksimov Y.M., Mukasyan A.S., Rogachev A.S. and printed by Elsevier Inc. 2017 (Borovinskaya *et al.*, 2017) and a book written by Rogachev A.S. and Mukasyan A.S., "*Combustion for Material Synthesis*" published by CRC Press in 2014 (Rogachev and Mukasyan, 2014).

Basic Features of SHS

General Approach

SHS reactions join two important phenomena: (1) combustion occurring in the system due to an exothermic chemical reaction and (2) simultaneous/sequential formation of the final product. To describe the basic features of the SHS reaction from the combustion point of view, we can use a simple cybernetic scheme treating SHS as a thermal system (Figs. 1 and 2).

Let there be an exothermic reaction (I) which proceeds with the release of heat (II). The reaction is carried out in a thermal system consisting of an external heat source (III) supplying heat and a heat removal system (dissipating) (IV) (Lis, 1994).

If the rate of heat removal from the system is greater than the rate of heat transfer outside from the reaction, then the thermal conditions of the reaction are determined by the relationship between the heat supplied from the outside and the heat that is released and removed. Under thermal equilibrium, the reaction proceeds at a constant temperature. By controlling the outside temperature, we can control the course of the reaction, and so its speed, degree of conversion, etc. This is a typical case for most of the chemical reactions.

Fig. 1 A schematic picture of self-propagating high-temperature synthesis (SHS).

Fig. 2 The idea of SHS as a thermal system.

However, if the rate of internal heat generated is greater than the rate of heat dissipated, then the heat can be accumulated in the system causing a temperature increase. In the case of a thermally activated reaction, this increases the reaction rate and, consequently, further increases the rate of heat release. There is therefore positive feedback causing a gradual acceleration of the reaction rate. This moment is called “ignition”. The reaction continues until the raw substrates are completely worn out in the reacting system. The degree of positive feedback is determined by the dependence of the reaction rate on the temperature, which in the case of chemical reactions can be taken as the relationship of the Arrhenius type. The parameter controlling the process is reaction activation energy. The higher the activation energy, the greater the self-heating capacity of the system. At the same time, it is necessary for the reaction to proceed under conditions as close to adiabatic as possible.

A characteristic feature of the SHS reaction is the need for thermal initiation, i.e., ignition, for which an external heat source is used. Before the ignition, the process has a traditional character: it is slow and is controlled by heat supplied from an external source. From the moment of ignition, the combustion process runs rapidly and spontaneously and is practically not controlled by external factors (Fig. 3) (ISMAN, 2020, Munir, 2001).

Two different ignition techniques are possible to start combustion during the SHS, as illustrated schematically in Fig. 4. The first, more typical, case is if the SHS is initiated in one place of the reacting system by using of a high-temperature heat source, i.e., an igniter. As shown in Fig. 4(a), the reaction “ignites” when in contact with a high-temperature igniter and then the high-temperature reaction front is formed, propagating through the entire system. Different high-temperature heat emitters, like resistant wire, termite reaction, laser beam, etc., can be used as the “igniter”.

The second type of ignition is schematically shown in Fig. 4(b). With the use of an external heat source will bring the whole reacting system to a high temperature, which can lead to spontaneous ignition in the entire volume. Such a case is called “thermal explosion”. In each of the two described cases, the end result is a completely reacted system.

After ignition, the reaction spreads from the ignited site over the whole volume of the reaction system. This characteristic of self-propagation is recognized as the next most important and defining feature of the SHS reaction. The propagating reaction front has

the character of a heat wave. A schematic picture of the reaction front is shown in [Fig. 5](#) ([Munir, 2001](#); [Merzhanov, 1990](#); [Merzhanov, 2005](#)).

The picture presents the profile of the temperature changes, the yield of conversion and the rate of heat release in the volume element of the system through which the reaction front passes. A characteristic feature for SHS processes is a narrow reaction zone, which practically has a dimension of the order of millimeters. At high rates of wave propagation, the process has a very intense nature with very high reaction rates, high temperatures, high temperature gradients and close to adiabatic nature. In real-world SHS processes, the reaction front propagation rates reach an additive, the temperature increase rates up to 100°C/s , and the temperatures rise up to 4000°C . At the same time, it is rather safe because the amount of heat emitted by the whole system in a unit of time is small.

The main task in implementing each SHS process is to ensure stable wave propagation. Wave parameters such as propagation speed, front width, maximum temperature and temperature distribution are determined by the physicochemical characteristics of the system and have a decisive impact on the resulting product. It should be noted that the conditions of “thermal explosion” can also be treated as a process in which heat wave propagation occurs, but the place of its initiation and the way of its course are more difficult to control.

A typical reaction system in the case of SHS is a mixture of powders in a solid state – “solid state combustion”. A combustion reaction with the participation of a gaseous reactant (oxygen, hydrogen or nitrogen) of the “filtration combustion” type is also

possible, which is schematically shown in Fig. 6. One solution in which one of the reactants is in a liquid state (“liquid combustion”) as well as a whole range of mixed systems are also possible.

In summary, it can be stated, that the SHS reaction can be carried out in a system in which a strongly exothermic chemical reaction takes place with high activation energy; the thermal conditions should ensure that the entire system or part of it is heated to the temperature at which the combustion type reaction will be initiated; the reaction front formed during combustion must be able to spread throughout the entire system, in addition it is preferred that the combustion takes place in an adiabatic-closed system.

Obtaining the Final Products by Structural Transformation

SHS technologies use the combustion effect to obtain a material, so the main problem is to learn and control the mechanism of structural transformation phenomena occurring in the system and causing the formation of the final product. There are two main mechanisms of the final product formation during the SHS process: equilibrium and nonequilibrium mechanisms (Maksimov, 2017).

For the equilibrium mechanism, the chemical changes of a green mixture in the combustion wave and the structure formation of a final product are considered to occur simultaneously. In this case, combustion and structure formation are strongly dependent on each other. The non-equilibrium mechanism corresponding to the condition describes a more complex structure and the processes can proceed one after the other. Here the combustion process does not directly influence the structure formation in the reaction products and the formation occurs far behind the front of the exothermic reaction. It can happen that the mechanism is mixed and the mechanism of combustion was equilibrium for one of the intermediate products and non-equilibrium for another product.

The study of the details of the reaction mechanism can be carried out using many techniques, also used in situ, such as: video recording, thermocouple measurement, thermography, XRD, SEM, TEM, neutronography, etc. (Rogachev and Mukasyan, 2017). A schematic diagram of the experimental SHS study in laboratory conditions is given in Fig. 7.

To learn and identify the mechanism of a reaction, the techniques of “freezing” the reaction front using different quenching techniques are very useful. They are followed by a *post-mortem* analysis of the microstructure of this area of the front including its chemical and phase composition. This allows the analysis of the phenomena occurring during SHS and the formation of the final product. Such phenomena are usually very complex and consist of, for example, parallel or sequential processes like chemical reactions occurring on contacts of grains, melting, evaporation, dissolution or crystallization phenomena.

An example of the complexity of the process is the mechanism identified by the authors which is close to those observed during the SHS preparation of SiC (Pampuch *et al.*, 1990; Pampuch *et al.*, 1991) during the SHS preparation of Ti_3SiC_2 , i.e., one of the so-called “MAX phases”, triple carbides with interesting properties (Barsoum and El-Raghy, 2000). This synthesis is possible (Lis *et al.*, 1993) by the SHS reaction in the $\text{Ti} + \text{Si} + \text{C}$ powder system according to the equation:

This process was carried out in the reactor whose diagram is shown in Fig. 8(a), and the temperature profile obtained as a result of the exothermic reaction is shown in Fig. 8(b). The self-heating of the system leads to a temperature in the reaction front up to a

level of 1800°C. The cross section of the frozen reaction front is shown in Fig. 8(c). The analysis of the phenomena occurring in the course of the reaction led to the identification of the reaction mechanism. It was detected, that SHS starts with a primary reaction between Ti + C particles which rapidly increase the temperature in the front. Then metallic reactants melt rapidly and form a Ti–Si liquid which dissolves the carbon. The formation of the SHS Ti_3SiC_2 product occurs by crystallization from the molten alloys. Ti_3SiC_2 + TiC mixture is found in the final SHS product. It is shown in Fig. 8(d). By controlling the SHS parameters, the optimum conditions for a formation product with more than 95% of Ti_3SiC_2 in the product with the rest of TiC can be achieved.

SHS Classification

The SHS system is a broad concept encompassing various synthesis techniques but having common characteristics as combustion. Different SHS phenomena can be classified taking into account various process features, for example with regard to (ISMAN, 2020):

- Method of ignition (thermal explosion, local ignition, mixing method).
- Reagent type (solid phase combustion, gas + solid phase combustion, liquid phase combustion, mixed combustion).

- Chemical reaction type (synthesis from elements according to the scheme: $A + B = AB$, exchange reactions: $AB + C = A + BC$ (e.g., thermite reactions), synthesis from compounds: $AB + CD = ABCD$, decomposition reactions: $AB = A + B$, etc.).
- Type of the obtained compounds (carbides, nitrides, oxides, borides, composites, ...).
- Type of the resulting product: (powders, sintered porous matter, dense polycrystals, layers, single crystals).
- Way of carrying out the process (free combustion, SHS + hot pressing, SHS + isostatic hot pressing, SHS + centrifugal forces, SHS + SPS, SHS + laser synthesis etc.).
- Ignition method (membrane heating, resistance spirals, electric arc, laser, chemical igniter, detonation energy).
- Nature of wave propagation: (stationary, oscillating, spin, spontaneous).
- Products application (alloys, structure ceramics, functional ceramics, refractories, abrasives, biomaterials, ...).

Modeling of SHS

Due to the very well-developed mathematical apparatus enabling the description of physicochemical phenomena occurring during SHS, there are many possibilities for their simulation and modeling. Such works were the basis of the initial research on SHS and are currently being developed, in particular thanks to the development of computer techniques. Modeling allows, among other things, to determine the potential possibility of a process in the SHS mode, the nature and conditions of ignition, the thermal waveform including the temperature and time changes, the nature and stability of combustion, etc. With the development of knowledge about physicochemical phenomena occurring during combustion, these models in addition to the phenomenological approach increasingly more frequently take into account such processes as chemical reactions and their sequence, evaporation, melting and dissolution, gas filtration and transport, crystallization and recrystallization or sintering. There are many works in this area summarized in the encyclopedic literature (Borovinskaya *et al.*, 2017; Rogachev and Mukasyan, 2014).

For applications of the models in the design of material technologies, three basic approaches are presented:

- (1) Determination of the “adiabatic temperature”, i.e., the maximum temperature to which the SHS system can heat up,
- (2) Models of the “thermal ignition” type of SHS,
- (3) Models of the self-propagating SHS “thermal wave”.

Adiabatic Temperature of SHS

The simplest model analysis of the SHS phenomenon can be the calculation of the reaction temperature based on the thermochemical approach. This type of analysis allows to determine the potential possibilities of the system to achieve high temperatures by self-heating and, at the same time, allows to analyze the influence of some parameters on this course. The analysis of the model temperature course in the SHS reaction can be carried out by means of thermochemical calculations starting from the balance of the heat released and absorbed in the system, assuming the adiabatic nature of the process (Lis, 1994).

The SHS-type exothermic chemical reaction begins at T_0 . If we assume adiabatic conditions, due to the self-heating of the system, the temperature of the system gradually increases. The amount of the heat released from the beginning of the reaction can be presented by the following Eq. (2):

$$Q_1^T = \int_{x=0}^x |\Delta H_T^r| dx \quad (2)$$

where:

x – the degree of reaction over time t at temperature T ,

ΔH_T^r – change in reaction enthalpy at temperature T .

If the process is adiabatic, the heat is completely absorbed by the system and heated to the temperature T of the whole system, i.e., substrates, products and possibly inert substances, as well as covers the endothermic phenomena that can occur during the process, such as melting, phase transformations, etc. The total heat absorbed in the system until (x, T) is equal to:

$$Q_2^T = \int_{x=0}^x \int_{T=T_0}^T \left(\sum_i n_i c_{pi} + \sum_k \int_{l=0}^l [\Delta H_k^m] dl \right) dT dx \quad (3)$$

where:

c_{pi} – molar heat of the i -th component,

n_i – the amount of moles of the i -th component,

ΔH_k^m – enthalpy of melting (transformation) of the k -th component,

l – the degree of melting (transformation) of the k -th component at the moment (x, T) .

Assuming that at the temperature T :

$$Q_1^T = Q_2^T \quad (4)$$

Table 1 Adiabatic temperatures of selected chemical reactions

SHS reaction	Adiabatic temperature $T_o = 25^\circ\text{C}$
$\text{Si} + \text{C} = \text{SiC}$	1690
$\text{Si} + 4\text{B} = \text{B}_4\text{C}$	980
$\text{Ti} + \text{C} = \text{TiC}$	3020
$\text{Ti} + 2\text{B} = \text{TiB}_2$	3150
$\text{Ti} + 2\text{Si} = \text{TiSi}_2$	1690
$\text{Ti} + \text{Si} = \text{TiSi}$	1720
$3\text{Si} + 2\text{N}_2 = \text{S}_3\text{N}_4$	4980
$\text{Al} + 1/2\text{N}_2 = \text{AlN}$	2900
$3\text{Ti} + \text{B}_4\text{C} = \text{TiC} + 2\text{TiB}_2$	2680
$4\text{Si} + \text{C} + 2\text{N}_2 = \text{SiC} + \text{S}_3\text{N}_4$	2850
$3\text{Ti} + \text{Si} + 2\text{C} = \text{T}_3\text{SiC}_2$	1930

**Fig. 9** A model schema for the thermal explosion mode of SHS.

and knowing all thermodynamic data, we can calculate the relationship between x , T and l at a given stage of reaction. If the system has reacted completely, i.e., $x=1$ and $l=1$, we can calculate the maximum attained temperature T of the system called the “adiabatic temperature T_a ”.

Selected results of such calculations are presented in [Table 1](#).

SHS Reaction in the “Thermal Explosion” Mode

Thermal explosion models can be derived from the analysis of combustion phenomena and can be used for SHS reactions initiated both by the method of thermal explosion and under self-propagation conditions. The analysis usually starts with a very simplified geometric model of the system, such as the one presented in [Fig. 9](#) ([Lis, 1994](#)).

The basic geometry is usually taken as an infinite cylinder with a radius r_0 . It is assumed that the system is homogeneous and has a density ρ , specific heat δ and thermal conductivity of λ , and is held at an initial temperature T_o .

The system is exposed to an external heat source under the assumed heating conditions, as well as to heat transfer with the environment (p). The thermal behavior of the model in these conditions can be described based on the Fourier equation type (5).

We assume that the system heats up as a result of heat release from the exothermic chemical reaction Q_w (Eqs. (6) and (7)) and by means of other internal heat sources. In general, this gives the heat balance of the equation type (8).

$$c\rho \frac{\partial T}{\partial t} = \lambda \nabla^2 T \quad (5)$$

$$Q_w = k(T, \eta) \quad (6)$$

$$\frac{\partial \eta}{\partial t} = k(T, \lambda) = k_0(1 - \lambda)^n = \exp\left(-\frac{E}{RT}\right) \quad (7)$$

$$c\rho \frac{\partial T}{\partial t} = \lambda \nabla^2 T + Qk(T, \eta) + f(t) \quad (8)$$

where:

T – temperature, c – specific heat, ρ – density, t – time, k – chemical reaction rate, η – reaction progress rate, Q reaction heat, $f(t)$ efficiency of internal non-chemical heat sources, k_0 – pre-exponential factor, n – reaction order, E – activation energy.

By solving the above system, assuming specific initial and boundary conditions, it is possible to simulate most cases of the macroscopic behavior of systems in which SHS occurs. Typical solutions look for relationships describing the temperature changes and the degree of reaction progress as a function of time. The system of the above equations has no analytical solution, but many numerical solutions or simplified analytical methods are used.

As an example of the description of the behavior of the system in the method of thermal explosion, let us give a model developed by the author and used to describe the SHS reaction of obtaining silicon carbide by synthesis from elements (Lis, 1994). The theoretical calculation is presented in Fig. 10 and, for comparison, the actual measured temperatures obtained during the SHS synthesis of SiC powders using the “thermal explosion” mode are presented in Fig. 11.

SHS “Thermal Wave” Modeling

Heat wave models are derived in many studies on the propagation of flames in burning gases (Borovinskaya *et al.*, 2017; Zeldovich, 1948). In the combustion process in a homogeneous system, a stationary wave propagates at a velocity u described by the general equation type (9). This wave is the result of an exothermic chemical reaction occurring in the system, whose thermal efficiency W can be determined by the relationship (9):

$$u = A(T, \eta) \exp\left(-\frac{E}{RT}\right) \quad (9)$$

where:

u – velocity of combustion front, T – temperature, η – degree of reaction conversion at temperature T , A – parameter dependent on T and η , E – activation energy, R – gas constant.

Fig. 10 The theoretical combustion temperatures in the Si + C system ignited by “thermal explosion”.

Fig. 11 The experimental measured combustion temperatures in an Si + C system ignited by “thermal explosion”.

This wave is the result of an exothermic chemical reaction occurring in the system, whose thermal efficiency W can be determined by the relationship (10), where n is a concentration of substance:

$$W = Qnpk_0 \exp\left(-\frac{E}{RT}\right) \quad (10)$$

If a reference system moving with a reaction front is adopted, such a process can be described by the equations:

$$\lambda \nabla^2 T - c\rho u \nabla T + Qnpk_0 \exp\left(-\frac{E}{RT}\right) = 0 \quad (11)$$

$$D \nabla^2 n - u \nabla n - k_0 n \exp\left(-\frac{E}{RT}\right) = 0 \quad (12)$$

Depending on the of the adopted procedure, the above system has several forms of solutions (Borovinskaya *et al.*, 2017; Maksomov *et al.*, 1984; Degreve *et al.*, 1987), so numerical methods are commonly used to solve it. The functions of temperature distribution are obtained, which take simple form as in Fig. 4 or more complex profiles (Merzhanov, 1990).

By solving the system of equations analytically, a relationship describing the speed of heat wave propagation can be obtained, e.g., for a one-dimensional medium it has the form of (Khakin and Merzchanov, 1966):

$$u^2 = f(n) \left(\frac{ck}{\rho}\right) \left(\frac{RT^2}{E}\right) k_0 \exp\left(-\frac{E}{RT}\right) \quad (13)$$

One of the basic theoretical problems for SHS is the determination conditions of heat wave propagation stability (Bayliss and Matkowsky, 1990). The propagation of the wave can: (1) take place in stationary conditions with a constant speed, (2) be of the oscillatory type with different oscillation frequencies, whereby the oscillations may be of a pulsating or spin nature, (3) be unstable of the dying type.

Analytical work determines such cases, depending on the adopted models and process parameters. Newly developed works in this field introduce additional parameters to models such as more complex geometric shapes, various equations describing reaction kinetics, complex thermal conditions, etc. What is particularly interesting are the solutions departing from the assumption of homogeneity of the system and introducing elements of the actual structure of the system to models such as system dispersion, melting, evaporation or crystallization phenomena. The theoretical simulations are verified in practical SHS experiments, which allows the possibility of checking the SHS models and improving the SHS process control.

SHS State of the Art

Starting a brief review of the history of the SHS development, it should be stated that SHS techniques are based on violent exothermic chemical reactions, the most spectacular example of which are explosive reactions. The history of the development of

explosives begins in ancient China around 2000 BCE with the invention of gunpowder, leads through nitroglycerin, TNT and ends with fusion reactions (Anderson, 1989).

SHS reactions, however, have more in common with less violent combustion-like phenomena. In the combustion process itself, the theoretical foundations of SHS can be found. The theories of combustion, especially the combustion of homogeneous systems (gaseous fuels), were developed based on the fundamental works of Zeldovich, Siemionov and Frank-Kameniecki (Degreve *et al.*, 1987; Zeldovich and Frank-Kameniecki, 1938; Semionov, 1961) from the 1930s. They were continued in the works on the combustion of condensed systems in Russia (Novoshilov, 1962), from which Merzhanov work on the theory of solids combustion (Merzhanov, 1990) and the thermal wave theory originated. These works focused on the analysis of the thermal effects of processes were based on a phenomenological approach and mainly concerned mathematical modeling.

In the cited fundamental work by Merzhanov *et al.* (1967), for the first time attention was drawn not to the use of heat or light from the combustion process but to the waste product ("ash") resulting from combustion. It was shown that the compounds formed during combustion can be treated as the final product of the process.

It should be noted, however, that this approach involving the use of the effect of the exothermic reaction and the phenomenon of self-propagation in chemical synthesis processes is found in the chemical literature of the nineteenth century. The review of these works was carried out by Hlavacek (1991). First at all, we should consider the nineteenth-century works of Berzelius (1825) and Moissan (1979) in which the preparation of oxides and nitrides by methods of metal combustion in gases was described. However, the historical creator of the combustion method of material synthesis was in fact Goldschmidt (Goldschmidt, 1895), who in 1895 for the first time described the so-called aluminothermy method, which consists in obtaining metals or alloys by reducing their oxides with the help of powder metallic aluminum. He characterized the phenomenon of self-propagation occurring in this case in condensed systems, based on the fact that after initiating the reaction in one place, it propagated spontaneously throughout the entire system. The temperatures achieved by the self-heating of the reacting substances were very high, i.e., on the order of 3000°C. The aluminum-thermic and similar magnesia-thermal methods in various variants were used in chemical technology and technique (incendiary substances, photography). Other exothermic reactions occurring in condensed systems described in the literature were the reactions of metals with sulfur and phosphorus studied in France (Fonze-Diacon, 1900). The work on obtaining hydrides by burning metals in hydrogen conducted in Germany (Kellenberg and Kraft, 1902) and the United States (Alexander, 1941) should also be mentioned here. The use of exothermic reactions as heat sources in the processes of obtaining materials was proposed for applying ceramic layers, in processes of the type of chemical hot-pressing, reaction-pressing or in various so-called variants chemical ovens.

The undeniable merit of Russian scientists (Merzhanov, Borovinskaya and others) was combining the rich scientific achievements of the theoretical direction of the study of combustion phenomena with the formation of structure products. It should be noted that in the 1980s SHS technologies were recognized as one of the priority achievements of the Soviet Union materials science, which was demonstrated by allocating corresponding funds for the synthesis of materials by SHS. They are mainly concentrated at the Institute of Structural Macrokinetics and Materials Science of the Russian Academy of Sciences (ISMAN) in Chernogolovka near Moscow (ISMAN, 2020). The main research was concentrated on synthesis of: refractory borides, nitrides and carbides (Borovinskaya, Mukasyan, Amosov, Prokudina, Levashov), casting alloys (Sanin, Yukhvid), ceramic-metal and ceramic-ceramic composites (Amosov, Levashov), MAX phases (Rogachev, Sytchev), complex oxides (Balashov, Barinova), organic materials (Klimchuk), and others materials.

The research centers founded in the former Soviet Union are still the leading research centers in the field of SHS globally. Since the collapse of the Soviet Union, the following SHS centers have remained active in Russia, namely: Institute of Structural Macrokinetics and Materials Science, ISMAN RAS; National University of Science and Technology MISIS Moscow, The Scientific-Educational Center of SHS; Tomsk Scientific Center of RAS and Samara State Technical University. SHS is also very explored in Armenia (Kharatyan, 2017), Kazakhstan (Ksandopulo *et al.*, 2017), Belorussia (Khina, 2017), and Georgia (Onashvili, 2017). A detailed description of the achievements in this area can be found on the ISMAN web-page (ISMAN, 2020), where information about appropriate monographs (Merzhanov, 2005) and others are available.

The information on SHS in the USA can be found in the review by Puszynski (2017). In the United States, the first reported research utilizing the self-sustaining character of thermite condensed-phase reactions was conducted by Walton and Poulos (1959) in the mid- and late-1950s. More significant research efforts were undertaken in the United States from the early 1980s. In 1982, McCauley *et al.* (1982) and Holt and Kingman (1982) published new results in the area of combustion synthesis, which generated interest at several universities and US government laboratories. The scope of research in American centers covers a whole range of problems in the field of SHS, from basic model considerations to technological studies. In the field of modeling, the works of Matkowsky (Bayliss and Matkowsky, 1990) and the group led by Hlavacek and Puszynski (Degreve *et al.*, 1987) deserve to be emphasized. In California (Los Alamos, Davis), the work led by Holt and Munir is focused on nitride systems with emphasis on studying nitriding phenomena and process mechanisms (Munir, 1993). Nitride systems are also studied at SUNY Buffalo, where the focus is on using SHS to obtain powders and ceramic products on an industrial scale (Hlavacek, Puszynski, Majorowski, Agrafiotis, Lis) (Agrafiotis *et al.*, 1990). These works are currently being continued and developed by Puszynski at the School of Mines and Technology, S. Dakota. A strong research center for SHS was established at the University of Alfred in 1989, which brought together scholars from other centers (Spriggs, McCauley, Stangle). Other significant centers in this field include the University of Notre Dame (Varma, Mukasyan), the University of Texas, Brausville (Rogahov), Anny Materials Research Lab, Watertown (McCauley, Croft); RPI, Troye (German); Ceramtec, Saint Lake City (Cutler); General Sc. Inc. (Rilcy); ART Buffalo (Blakely) and others.

Japanese research activities on the SHS process were started in 1979 by research and development studies on ceramic linings with thermite reactions performed inside a centrifuged hollow pipe (centrifugalthermite process). The Japanese SHS-oriented investigations accelerated in 1982 under the influence of J.F. Crider's review paper published in *Ceramic Engineering and Science Proceedings* (Crider, 1982). The works on SHS in Japan have been conducted since 1984 in several centers. The most interesting research seems to be carried out at Osaka University on the synthesis of nitride powders (Hirao *et al.*, 1987a) and the synthesis of materials using an original technique combining SHS synthesis, "chemical furnace" and hot isostatic pressing (SHS-HIP) (Miyamoto) (Lis *et al.*, 1995). The latter solution allows obtaining dense materials such as TiB₂, TiC, SiC and composites in one technological cycle. The next achievement in this field is the successful application of this method to obtaining the so-called "functionally gradient materials" (FGM), which are layered materials with a continuous transition from metal to ceramics (Koizumi, Miyamoto). The Japan Research Association of Combustion Synthesis (ORACS) was established in 1987 with members from 5 universities, 4 national laboratories, and 29 industries. For the Japanese achievements in SHS, see the review prepared by Odawara (2017).

Apart from Japanese works, several centers in Asia are involved in working on SHS, mainly in China, Turkey, South Korea, India and Taiwan. The SHS research in China began in the late 1980s at Wuhan University and the Beijing University of Science and Technology. In WUT (Fu), the main research directions are SHS-based fast synthesis and sintering materials, and SHS for thermoelectric materials. At the Beijing University of Science and Technology (Ge), the main specialization is SHS FGM for tube coatings, and the combination of sol-gel and SHS. At the Harbin Institute of Technology, the research activity is focused on SHS for high-temperature multiphase ceramics. SHS is also developed in Shijiazhuang Mechanical Engineering College, Technical Institute of Physics and Chemistry. More detailed information can be found in the Fu review (Fu, 2017).

The beginning of metallothermic reduction-based studies in Turkey was a result of studies on the carbothermal synthesis of advanced ceramics (e.g., B₄C) and ferroalloys (e.g., FeB) at Istanbul Technical University (ITU) in the late 1980s. In the SHS field, the first study was on the determination of the optimum SHS parameters for the synthesis of TiB₂ in 2004. Many SHS studies have been conducted at ITU concerning the SHS of borides and carbides, such as TiB₂, B₄C, and ZrB₂, and the metallothermic reduction of iron and its alloys, such as carbon-free Cr-Ni-Mo-Ti-containing alloys and shape memory alloys. Middle East Technical University (METU) in Turkey has also contributed to the literature on volume combustion synthesis (VCS) (Yucel review (Yucel, 2017)).

SHS processes were introduced in Korea in the early 1995. A number of universities and organizations were involved in the research activity focused on the production of various compact and porous inorganic materials. The list of organizations involved in the SHS activity and their main fields of interest is as follows (Nersisyan *et al.*, 2017): Chungnam National University (nanostructured materials and LED phosphor powders), Korea Institute of Machinery & Materials (porous MoSi₂), Korean Atomic Energy Research Institute (TiC, SiC, and ZrC powders and C/SiC/C multilayer composite), Chonbuk National University (Mo-Si-SiC composite), Ulsan University (porous TiNi alloy), Hong Ik University (MoSi₂ and AlN); Pusan National University (AlN and ZrB₂), the Korea Institute of Geoscience and Mineral Resources (AlN powder), Changwon National University (SiAlON), Hanbat University (MoSi₂, SiO₂), Kyungnam University (TiC, SiC, WC, and composites), Sun-Moon University (TiC nanofibers) and Dong-A University (Ba-Zn ferrites).

The SHS methods are spreading in Europe, mainly in Italy, France, Spain, Poland Greece and Israel. The scientific output of the seven research groups that have been active in Italy over the past 20 years cover diverse classical topics in SHS, i.e., the combustion theory and modeling, structural macrokinetics and the synthesis of ceramics, intermetallics and composites. The main centers are: the University of Cagliari (Cao, Orru) (the SHS and field-activated combustion synthesis processes or their combination with ball milling or mechanical activation to synthesize various materials), the University Of Genoa (Ferretti) (combustion synthesis of various metal nitrides), National Research Council Ieni, Milan, Ing. (Zanotti) (SHS of Ti-Al, Ti-Ni and functionally graded materials (FGM)), the University of Pavia (Anselmi Tamburini) (SHS of various systems such as Ni-Al foils, Y₂O₃-ZrO₂, Ni/YSZ, ZrO₂, Zr-Si, Fe-ZrO₂, Cr-Si, metastable solid solutions, Ta-Si, Ti-Si, Co-Al, Nb-Al, metal-metal oxides, Ti-Al, Ti-Ni, and FGM) and the University of Sassari (Copcco, Mariani) (combustion of dioxins, herbicides, and hexachlorobenzene). A review of the Italian SHS activity was presented by Cao and Orru (2017).

In France, the major scientific SHS center is the University of Bourgogne in Dijon (Bernard). What is very interesting are in situ simultaneous infrared and time-resolved X-ray diffraction measurements conducted in order to study the self-sustained reactions. The other research included: (1) heat generation where the SHS reaction is used to generate heat as a "chemical oven"; (2) SHS of composites such as the dense NiAl-ZrO₂ composite, which can be produced by combining thermal explosion with a post thermal cycle and dense MoSi₂-Al₂O₃-based functionally graded materials (FGM) with different alumina contents, (3) repairing and coatings used to simultaneously repair and coat the Ni-based superalloy and (4) production of fully dense nano-intermetallics by reactive sintering in an SPS machine, testing of mechanical properties of the MAX phases prepared by SHS (Kozak *et al.*, 2019). More details can be found in the Bernard review (Bernard, 2017).

In Spain, the research on SHS began in 1991 with a joint project of ISMAN, Russia, United Technologies Corp. (UTC), and Tecnologia del Grupo INI (TGI, INI group). The Institute of Ceramics and Glass IGV-CSIC (Bernard) and the INASMET Technology Center also collaborated in this project as support centers. The aim was to produce a pilot plant for the production of powders by SHS: Si₃N₄, AlN, TiC, and Cr₂C. The goal was successfully accomplished and led to the creation of SHS Ceramics, S. A., the first Spanish company to obtain raw SHS materials. Currently, the work on combustion synthesis is ongoing in several new different directions, including field-assisted combustion synthesis and solution combustion synthesis. The obtained materials were meant for use in different fields, i.e., for structural applications, functional applications, and biomaterials. More details are contained in the review by Rodrigues (2017).

SHS was introduced to Poland in the 1970s at the AGH – University of Science and Technology, Faculty of Materials Science and Ceramics, in Kraków by Pampuch *et al.* (1989). A majority of their works confirmed the applicability of SHS to the preparation

of sinterable non-oxide ceramic powders like SiC, B₄C, Si₃N₄, Sialons, Alons, MAXs, etc. The aim of the AGH-UST work was to prepare single-phase sintered polycrystals as well as multiphase ceramic composite materials from SHS derived powders. Dense polycrystals with interesting properties were synthesized for materials in numerous explored systems: Si–C–B, Si–C–N, Si–Al–O–N, Si–Al–N–C, Al–O–N, Ti–B–C, Ti–Si–C, Ti–Si, Ti–Al–C, Ti–Si–C–N and Ti–Al–C–N. The second SHS research effort took place at the Center of High Pressures UNIPRESS of the Polish Academy of Sciences in Warsaw (Skibaska). These investigations, performed from the 1980s, were focused on the preparation of silicon nitride powders by the SHS method. The next research line opened at the Laboratory of Nanomaterials Physics and Chemistry. The Department of Chemistry, Warsaw University (WU) (Huczko) has conducted studies on SHS and solution combustion synthesis (SCS) applications, including the discovery of SHS of SiC nanofibers. The work on the application of combustion effects and explosive phenomena to the synthesis of materials is a subject of research at the Faculty of Advanced Technology and Chemistry, the Military University of Technology (WAT), in Warsaw (Cudziło, Jużwik). More details are available in the review by Lis (2017).

There is extensive factual literature on the work on SHS. The following works, besides the cited ones (Borovinskaya *et al.*, 2017; Rogachev and Mukasyan, 2014), can be recommended as the most important studies in this field: (Pampuch and Stobierski, 1991; McCauley, 1990; Merzchanov, 1990; ISMAN, 2020).

Review of the Materials Prepared Using the SHS Methods

The advantage of SHS as a technique for obtaining materials that is often brought to the fore is its energy-saving nature. The maximum use of the heat of internal exothermic reactions allows to save approx. 50%–98% of the total energy necessary for synthesis (Borovinskaya, 2017). As regards this aspect, the SHS reactions can be classified into the most energetic explosive reactions and typical ceramic technology processes, such as sintering, which require the supply of large amounts of energy (Pampuch *et al.*, 1993).

The attractiveness of SHS techniques for the production of different materials, however, primarily results from a large variety of obtainable compounds and material forms. Examples of chemical compounds obtained by the SHS techniques presented in the literature are summarized in Table 2. The presented list contains more than 200 compounds and is still open. An analysis of the literature indicates that currently the list of various materials obtained using SHS far exceeds 1000 examples. The amount of compounds synthesized by SHS is still being expanded, especially by increasingly complex multiphase materials.

In the SHS method, chemical compounds can be obtained as materials in various forms, depending on the type of material and the SHS technique used. One of the possible classifications of materials obtained by the SHS method is as follows:

(1) Powders

The basic SHS process of the free combustion method produces materials in the form of powders. The SHS powder products are in more or less agglomerated form with different chemical purity. They usually require further processing, such

Table 2 A list of chemical compounds obtained by self-developing high-temperature SHS synthesis methods

Groups of materials	Compounds prepared by SHS
Carbides	TiC, SiC, ZrC, TaC, NbC, WC, B ₄ C, HfC, Cr ₃ C ₂ , Mo ₂ C, SiC–B ₄ C, TiC–WC, W–Fe–C, TiC–Cr ₃ C ₂ , TiC–Mo ₂ C, Ti ₃ SiC ₂ , TiAl ₂ C
Borides	TiB, TiB ₂ , ZrB ₂ , NbB ₂ , TaB ₂ , CoB, HfB ₂ , V ₃ B ₂ , VB, VB ₂ , CrB, CrB ₂ , MoB, MoB ₂ , Mo ₂ B, Mo ₂ B ₅ , WB, W ₂ B, MoB ₄ , HfB ₂ , WB ₄ , ZrB ₂ –CrB ₂ , NiB, FeB, LaB ₆ , TiB ₂ –CrB ₂
Nitrides	Si ₃ N ₄ , α, β, γ sialons, AlN, TiN, TaN, ZrN, NbN, HfN, VN, BN, NbN, LaN, ScN, ErN, PrN, NdN, SmN, GdN, DyN, TbN, Si ₃ N ₄ –AlN, TiN–AlN
Silicides	MoSi ₂ , MoSi, Ti ₅ Si ₃ , ZrSi, TiSi ₂ , VSi, NbSi ₂ , TaSi ₂
Intermetallics	TiAl, ZrAl, NiAl, Ni ₃ Al, Ni ₂ Al ₃ , NdAl, CuAl, TiFe, TiNi, TiCo, VAl, NbGe, Nb ₃ Al, TiNi, WAl, ZrPT ₃
Hydrides	TiH ₂ , ZrH ₂ , NbH ₂ , SeH ₂ , VH ₂ , VH ₃ , LaH ₂ , PrH ₂ , NdH ₂ , SmH ₂ , SmH ₃ , GdH ₂ , TbH ₂ , TbH ₃ , DyH ₂ , DyH ₃ , MoH ₂ , MoH ₃ , TiZrH ₂ , ZrCoH ₃ , ZrCoH ₅ , ZrNbH ₅ , TiCoH ₃
Sulphides	WS ₂ , MoS ₂ , TaS ₂ , NbS ₂ , La ₂ S ₃ , WNbS ₂ , LaTaS ₃ , LaNbS ₃ , PrNbS ₃ , NbNdS ₃ , TbNbS ₃ , DyNbS ₃ , YNbS ₃ , PrTaS ₃ , NdTaS ₃ , TbTaS ₃ , DyTaS ₃ , ErTaS ₃ , EuTaS ₂ , EuNbS ₂ , MoS ₂ , MoS ₂
Selenides	WSe ₂ , MoSe ₂ , TaSe ₂ , NbSe ₂ , WNbSe ₂ , MoNiSe ₂
Phosphides	AlP, CuP, NbP, FeP, MnP, TiP, CrP, Co ₂ P, Fe–Mo–P, Fe–Mn–P
Oxides	BaTiO ₃ , PbTiO ₃ , PbZrO ₃ , BaZrO ₃ , YAlO ₃ , LiTaO ₃ , MrAl ₂ O ₄ , NaTaO ₃ , KTaO ₃ , BaNaTa ₅ O ₁₅ , Bi ₄ V ₄ O ₁₁ , Bi ₄ Fe ₂ O ₃ , Bi ₄ Ti ₃ O ₁₂ , Bi ₃ TiNbO ₉ , Bi ₃ TiTaO ₉ , BaBiNbO ₉ , PbBi ₂ Ta ₂ O ₉ , BiCu ₃ O ₁₂ , Bi ₂ MoO ₆ , LiNd(MoO ₄) ₂ , PbMoO ₄ , PbWO ₄ , Li(MO ₃) ₂ , Cd ₂ Mo ₃ O ₁₂ , Ba ₂ NaNb ₅ O ₁₅ , Ba ₂ KNb ₅ O ₁₅ , BaNb ₄ O ₆ , YBa ₂ Cu ₃ O ₇ , CoFe ₂ O ₄ , BaFe ₂ O ₄ , BaFe ₁₂ O ₉ , Li ₂ Fe ₂ O ₄
Alloys	Cr–Ti, Cr–Zr, Mo–Ti, W–Mo, Ti–Zr, Mo–Nb, W–Nb, Zr–Co–Ni, Hf–Nb–Ti, Ti–Cr–Sc–W
Triple compounds	MAX phases: Ti ₃ SiC ₂ , TiAlC ₂ , TiSiC, TiAlN, TiAl ₂ N, TiAlN, TiC _x N _{1–x} , ZrCrN, NbC _x N _{1–x} , TaC _x N _{1–x} , Ti–C–H, Ti–N–H, Zr–N–H
Composites	WC–Co, VN–Fe, Ti–TiB ₂ , Ti–SiC, TiC–Ni, ZrB ₂ –Fe, TiC–MnNi, TiC–Mo–Re, (Cr–Ti–C)NiMo, (W–Ti–Cr–C)NiCo, Al ₂ O ₃ –TiC–Fe, SiC–Si, SiC–B ₄ C, TiC–TiB ₂ , SiC–Al ₂ O ₃ , Al ₂ O ₃ –B ₄ C, Al ₂ O ₃ –MoB, Al ₂ O ₃ –AlN, AlN–AlON, AlN–Al ₂ O ₃ –AlON, Al ₂ O ₃ –TiN, Al ₂ O ₃ –VN, Al ₂ O ₃ –CrB ₂ , Al ₂ O ₃ –MoB ₂ , Al ₂ O ₃ –MoSi ₂ , MgO–MoSi ₂ , TiC–Cr ₂ O ₃ , TiC–MgO, Cr ₂ C ₃ –Al ₂ O ₃ –Ni, SiC–TiB ₂ –Al ₂ O ₃ , TiC–SiC, SiC–B ₄ C, TiC–Ti ₃ SiC ₂

as grinding and milling in the case of powders, which is aimed at obtaining materials by sintering or chemical treatment for powders using thermite methods. However, there are SHS solutions that allow obtaining fine powders and even nano-powders by using additives to prevent agglomeration and junction of particles (Borovinskaya, 2017).

Powders from the SHS synthesis can be used mainly:

- As starting powders for obtaining ceramic polycrystals by sintering, HP, etc. (Pampuch *et al.*, 1993),
- As abrasive powders (Merzhanov *et al.*, 1981; Prokudina, 2017),
- For the production of cemented carbides (Konyashin, 2014).

(2) Porous materials

The high temperatures at which SHS processes take place mean that the synthesis can occur simultaneously with the consolidation processes. At the same time, the chemical reactions occurring during sintering generally make full compaction difficult and prevent achieving high densities of materials. The additional factors limiting the achievement of high densities of synthesis products are: short process times, gas evolution and large temperature gradients. Typically, polycrystalline porous materials with a porosity of 5%–70% are obtained with the SHS method. It is promising as regards producing materials with controlled porosity for applications as filters, catalyst substrates, biomaterials etc. (Agnote *et al.*, 2017; Xanthopoulou, 2017; Potanin *et al.*, 2015).

(3) Dense materials

There are some solutions that increase the final densities during SHS, for example, running the process in a vacuum, introducing additives that increase the amount of the liquid phase during the synthesis or using external additional mechanical pressing. Such a combination of the SHS process and force pressing which allows for obtaining dense materials in one stage is currently a well-developed field of the SHS applications. The SHS process can be carried out in a matrix under mechanical pressure HP or isostatic pressure HIP (Hirao *et al.*, 1987b) and Spark Plasma Sintering SPS solution (Ortu *et al.*, 2014; Koshiyama *et al.*, 2016). Examples of materials obtained by this method include dense polycrystals, superalloys, gradient materials FGM and ceramic composites.

(4) Thin foils, deposited and layers

Materials in the form of layers are obtained using SHS by both solid and gas phase combustion. In Japan, India, China, and Russia (Odawara and Ikeuchi, 1986; Kachin and Yukvid, 1992), technologies have been developed for the application of SHS using ceramic layers on metal pipes under centrifugal forces. SHS is also tested for the preparation of deposits in the form of thin foils and layers from superalloys, ceramics, gradient FGM, etc. (Rogachev, 2008; Kumar *et al.*, 2012). Powders obtained by SHS methods used as substrates in plasma deposition techniques are also of particular interest from the point of view of technology (Aruna *et al.*, 2013).

(5) Monocrystals

SHS conditions can be combined with zonal melting to produce a single crystal product. In more developed solutions, single monocrystals (Ohtani *et al.*, 1987) or single-crystallite form of powders, whiskers, nanotubes and fibers are obtained in this way (Wang *et al.*, 2010; Borovinskaya *et al.*, 2010).

(6) Joining and welding

SHS proved to be an effective and economically competitive method of joining various materials such as metal-metal, metal-ceramics, ceramics-ceramics using different “chemical welding” reactions (Mukasyan, 2017) and laser supported SHS (Rutkowski *et al.*, 2018).

SHS Technique Used for Ceramic Materials Technologies

Advantages of the SHS Method for Ceramics

Generally, the distinctive features recognized as the basic advantages of the SHS method are:

- (1) Energy saving based on the use of internal reaction heat,
- (2) High temperatures achieved by self-heating,
- (3) High heat wave propagation speeds enabling processes of very short duration time in seconds with high efficiency,
- (4) Relatively simple apparatus

Some limitations of the SHS method can be related to the problem of prices and the availability of raw materials. In SHS methods, processed powders, mainly metallic, are used as raw materials, which in some cases are relatively cheap and available in large quantities (e.g., silicon, aluminum, etc.). Hence, other methods of holding covalent powders, e.g., carbothermal methods, plasma synthesis, etc. using more easily available oxide or organic raw materials have undeniable advantages from this point of view. As regards the other reported SHS weakness, it is undoubtedly the difficulty of process control, especially during the scaling-up stage.

It can generally be said that the SHS technique can be particularly beneficial in ceramic production technologies. With the exception of carbon materials, ceramic materials in both conventional and advanced ceramics are in the form of chemical compounds. Both ionic and covalent bonds in ceramic materials have a high enthalpy of formation. Therefore, the reactions of the synthesis of ceramic compounds from elements are exothermic and have high activation energies. The transport processes, such as diffusion, are difficult in these materials as sintering causes problems, especially in the case of covalent compounds. Moreover, these processes require high temperatures as well as special technical treatment, e.g., HP, HIP, SPS, etc.

If the synthesis process and sintering take place simultaneously, as it occurs in the course of SHS, then the heat of reaction can be used to simultaneously heat the system to temperatures enabling consolidation. These processes are therefore highly energy-efficient. At the same time, the short duration of the phenomena associated with rapid heating and cooling of the system causes the whole process to acquire the character of “fast sintering, fast firing”, close to other flash methods of consolidation, such as Spark Plasma Synthesis SPS, Laser Manufacturing LM or Plasma Sintering PS. In addition, self-purification occurs under combustion conditions as a result of the evaporation of volatile impurities or the selection of admixtures in the liquid phase, which makes SHS attractive for ceramic processing.

Numerous studies have found that because of the rapid high-temperature reaction conditions with ultrafast heating and cooling rates, the specific mechanisms of the reaction can occur, which results in solid solutions, multiphase composition, non-equilibrium phases, etc. Due to this, in some cases, it is not easy to obtain the possibility of preparing unique phase compositions by other more conventional methods. SHS can be a method for obtaining sintered nano and micro ceramic powders, active catalysts, biomaterials, thin layers, layered materials, etc. (Xanthopoulou, 2017; Pampuch *et al.*, 1993).

Potential advantages of SHS processes as methods of obtaining ceramic materials are associated with specific conditions under which the reaction takes place. These are:

- High temperature increase rates,
- High cooling rates,
- Specific reaction mechanisms,
- Processes of self-cleaning of the system from impurities

The special possibilities are:

- Obtaining ceramic materials with high chemical purity,
- Obtaining non-equilibrium phases and systems,
- Obtaining systems with high homogeneity,
- Obtaining composite multiphase materials, e.g., granular composites and such unique materials as gradient materials (FGM).

Principles in the Processing of Ceramics Using SHS

The goal of ceramic technology is to obtain products with particular properties, including appropriate dimensions and shape, surface state as well as mechanical, thermal, electrical, optical properties, etc. Considering the current state of knowledge and the development of SHS techniques, it can be stated that the technologies for obtaining ceramic materials can be divided into two basic types (Fig. 12(a) and (b)).

The best and most cost-effective solution is to obtain the finished product directly in a one-stage SHS process (Fig. 1(a); Lis, 1994; Amosov, 2017). In such a solution, as a result of SHS, powders, porous sinters, layers, coatings, single monocrystals and other forms of materials can be obtained, which, after any kind of mechanical processing, can be the used as the final product. The real problems are sometimes related to obtaining dense materials with a controlled microstructure. Generally, due to the rapid combustion phenomena and short process times as well as the potential for the evaporation of reagents, a typical SHS product is porous.

More dense materials also full compaction can be achieved by using a combination of SHS with simultaneous mechanical pressure, e.g., hot mechanical and isostatic pressing (HP/HIP SHS, reactive forging) (Hirao *et al.*, 1987a; Gutmanas and Gotman, 1999), high mechanical force (Forced SHS) (Levashov *et al.*, 2014), explosion detonation (Thadhani, 1993) or SPS (Ortu *et al.*, 2014). Techniques using other methods of applying various mechanical forces, such as centrifugal SHS casting (Yukhvid, 1992; Odawara, 1990), rolling SHS (Chernyshov *et al.*, 1993) or controlled gravitational field (Odawara, 1997), are also interesting. Also, conscious sintering support by using a controlled liquid phase can lead to the thickening of the synthesized material (Yukhvid, 1992).

Fig. 12 The preparation of materials by SHS: (a) one-step process, (b) two or multi step treatment.

Another approach is to use SHS-obtained ceramic powders as precursors to sintered products in a multistep technological treatment (**Fig. 14(b)**). On the one hand, SHS allows for relatively easy and cheap obtaining of simple and complex powders of such compounds as carbides, nitrides or borides in different forms, including nanopowders, whiskers or nanotubes (*Borovinskaya et al., 2010*). Secondly, these powders are characterized by high chemical and phase purity, and at the same time, they are active in sintering due to their non-equilibrium nature. In technology, they sometimes require an additional de-agglomeration stage in the milling process (*Pampuch et al., 1993*).

Because of the development of SHS, the synthesis of SHS powders is often combined with other techniques that support the processes of obtaining materials and controlling their properties. Interesting solutions include the so-called “chemically assisted combustion synthesis” (CACS) (*Kharatyan and Nersisyan, 2002; Amosov et al., 1992*), consisting in adding materials that cause additional chemical reactions thermally activating SHS or control the morphology of the final product to the synthesis. The same effect can be obtained by using additional reaction catalysts (*Kim and Wooldroge, 2001*). Recently, techniques combining SHS with mechanical activation processes and milling (mechanically activated SHS MS-SHS) have been developing, especially those used to obtain powders with thermite methods or powders of metal alloys (*Takacs, 2002; Kubatkina et al., 2008; Bernard and Gaffet, 2001*). To additionally support SHS, field-activated SHS, which is close to SPS and ultrasound (*Khina and Kulak, 2013*), are also used. SHS phenomena are used to obtain so-called energetic materials, which in the form of nanopowders can cause extreme changes in temperature or pressure in the course of violent reactions (*Puszynski et al., 2007*).

One of typical examples of a multi-steps SHS approach is schematically shown in **Fig. 13** in the laboratory process for obtaining ceramics based on the MAX phase Ti_2AlN for a structural application (ceramic armor). The basic chemical reactions used in a two-step SHS are as follows (*Chlubny et al., 2012*):

The presented developed process has the following unit operations:

- (1) Preparation of TiAl powder by the SHS method,
- (2) Mixing the TiAl powder with Ti powder,
- (3) SHS filtration combustion of the TiAl powder in nitrogen in a pressure reactor,
- (4) Milling the SHS product
- (5) Sintering in an HP press
- (6) Final machining of the product

Fig. 13 The multi-step process of obtaining the TiAl_2N product using SHS.

Application of SHS Methods in Technological Scale

The application of the SHS technique to obtaining materials has been used in many developed, patented and implemented technological solutions (Pampuch, 1999). There are three types of SHS production: pilot-scale, semi-industrial, and industrial-scale (Borovinskaya, 2017). The first pilot-scale and semi-industrial facilities appeared in Russia for obtaining of powders of carbides, borides, nitrides and composites i.e., consolidated materials from refractory compounds (ISMAN, 2020). Semi-industrial production appeared also in different countries: Japan, Kazakhstan, United States, China, and Poland. Based on semi-industrial production, industrial SHS facilities were developed. One of these was set up in Armenia for the manufacturing of high temperature heating elements based on molybdenum disilicide. The SHS production of nitrided ferroalloys and alloying additives was organized in Russia. One of the most significant achievements of the industrial application of SHS technologies is the production of ceramic powders in Spain and Russia, hard-alloyed tungsten carbide powders in Russia and pipes with corrosion-resistant internal ceramic coatings in China (Borovinskaya, 2017).

The broadest technology list is offered by ISMAN (Chernogolovka, Russia). (ISMAN, 2020). They classify SHS technologies divided into six categories:

- (1) SHS Powder Technology
- (2) SHS Sintering
- (3) SHS Force Compaction
- (4) SHS Metallurgy and SHS Technology of High-Temperature Melts
- (5) SHS Welding
- (6) SHS Technology of Gas-transport Coatings

These technological types are characterized by the following features:

- Low energy consumption (in most cases an additional energy is only necessary for initiating an SHS process,
- Simple technological equipment, its high productive capacity and ecological parameters;
- Decreased number of technological stages in comparison with conventional technologies;
- Feasibility of production lines adaptable to the production of different materials and items and amenable to mechanization and automation;
- Possible substitution of raw materials with cheaper ones for producing one and the same product;
- High technical and economical parameters of a great number of valuable materials and items for up-to-date engineering.

According to the information of authors from the ISMAN (ISMAN, 2020), more than 700 various inorganic compounds and materials have been obtained by the SHS methods and these technologies can be alternative to many traditional materials technologies, as shown in Table 3.

In conclusion, examples of ceramic materials obtained in the AGH UST using SHS technologies are presented in Figs. 14 and 15.

Hydrothermal Synthesis

Powder Synthesis Methods

Particulate materials play significant roles in technological developments and subsequently impact our daily lives. Their physical and chemical characteristics significantly affect their functionality properties and performance (Adair and Suvaci, 2000). Therefore, it is critical to control particle characteristics to fulfill the expectations of future technologies. Moreover, such particulate materials can exhibit novel properties by tailoring its physical characteristics. For example, when their size goes down to nanoscale then they demonstrate unique properties or particles with anisometric (plates, rods, etc.) morphology enable researchers to have access to novel anisotropic properties via texture development in advanced ceramics (Messing *et al.*, 2004; Suvaci and Ozer, 2005). Therefore, the powder synthesis methods should enable one to tailor the physical properties of particles.

The most widely utilized nonmetallic inorganic powder synthesis methods are mixed oxide solid-state reaction, liquid phase based methods such as coprecipitation and hydrothermal synthesis, and gas phase based methods such as vapor-phase reaction. Although the solid-state method is commonly used for powder synthesis, this method has many drawbacks such as low purity, large particle size, and broad particle size distribution. The vapor phase methods provide high purity powders but stoichiometry of the resultant particles can be poor and they exhibit usually high degree of aggregation. On the other hand, the liquid based methods can lead to improved control of the thermodynamics and kinetics involved in nucleation and growth processes. Therefore, growing particles of varied morphologies in those methods can be achieved by altering thermodynamic and kinetic parameters such as temperature, concentration of reactants, duration of crystal growth, and additives (Ring, 1996). High purity and better stoichiometry control are provided with the coprecipitation method; however, wide particle size distribution can be formed from submicron to micron size (Adair and Suvaci, 2001). Since the precipitation phase in aqueous media is usually not oxides but its hydrates, it should be calcined to achieve the final form prior to use of such particles and unfortunately this calcination step results in aggregation of fine particles. As a result, most of such powders should be milled to achieve fine particle size. Among the synthesis methods, hydrothermal synthesis has been widely utilized because it leads to powder with superior properties such as high purity, phase stability (stoichiometry), tailorable particle size, and narrow size distribution, and controllable morphologies depending on technological developments and hence demands in particle technologies. Hydrothermal synthesis involves direct formation of crystals from solutions in aqueous media at elevated temperature ($T > 25^{\circ}\text{C}$) and pressure ($> 100\text{ kPa}$). In this method, powders nucleate and grow in a controlled manner and subsequently result in crystallized particles with controlled size and morphology as well as low degree of aggregation/agglomeration. As an example, Fig. 1 shows various oxide particles with various morphologies spanning from cubes to rods synthesized by hydrothermal methods. In addition, coating of particles can be achieved by using hydrothermal synthesis to improve particle characteristics or to add new functionality to the substrate particle as shown in Fig. 2 where PbTiO_3 platelet is coated with BaTiO_3 particles. Besides allowing controllable material characteristics with stoichiometry, hydrothermal synthesis offers additional substantial benefits such as operating at low synthesis temperature, fast and flexible continuous or batch processing, large scale industrial production, cleaner processing routes, and not involving harmful organic solvents. In addition, energy consuming steps such as high temperature calcination and milling are not needed in this process. Consequently, hydrothermal synthesis can be considered as a green and energy efficient process. The assessment of the powder synthesis methods according to obtained particle characteristics are presented in Table 1.

Recent Activities in Hydrothermal Synthesis

Recently, various synthesis strategies for precise control of the hydrothermal synthesis conditions have been developed in order to tailor synthesised product characteristics in terms of size, shape and composition (Feng and Li, 2017). These strategies consist of internal factors related to the reaction system such as use of organic additives, templates, and substrates and the external environment's effects including but not limited to utilization of microwaves, electric field, or magnetic field during hydrothermal synthesis to get desired materials structure forms (Yang and Park, 2019). Such developments also contributed to earlier hydrothermal-based synthesis types and now hydrothermal synthesis has been used in many different forms as depicted as hydrothermal synthesis tree in Fig. 3.

During the last two decades, hydrothermal synthesis has become the key synthesis method for powder materials to obtain unique properties by tailoring their physical characteristics. Fig. 4 shows the number of publications on the hydrothermal synthesis for each year beginning from 2000. The data were collected from the Web of Science by using the key words *hydrothermal* and *synthesis*. As shown in Fig. 4, the number of published papers steadily increased to 2014; since then there has been a slight decrease but the numbers are still high. Accordingly, the total number of publications on hydrothermal synthesis since 2000 to date exceeds 11,000.

Among those published papers, an increasing number about continuous hydrothermal synthesis is very remarkable. More recently, scientists have worked diligently to demonstrate potential use of rapid continuous hydrothermal methods for production of inorganic materials. With continuous hydrothermal synthesis, manufacture of various nanomaterials can be scaled up for

Fig. 1 Scanning electron microscopy images of various oxide particles with various morphologies synthesized by hydrothermal method: (a) Cubic $\text{Pb}(\text{Zr}_{0.52}\text{Ti}_{0.48})\text{O}_3$ particles, (b) plate-like PbTiO_3 particles, and (c) rod-like ZnO particles.

Fig. 2 Scanning electron microscopy image of BaTiO_3 coated PbTiO_3 platelets.

commercial applications with controllable particle properties (stoichiometry, size, shape, porosity, etc.). The latest progress in continuous hydrothermal techniques was presented recently by some research groups (Dunne *et al.*, 2015; Darr *et al.*, 2017).

To investigate the impact of the external environment's effects on the synthesis and the properties of the nanomaterials such as semiconducting nanomaterials, scientists have designed and developed microwave, electric field, and magnetic field assisted hydrothermal methods. The increase in number of the published papers on microwave assisted hydrothermal synthesis sorted by year is shown in the inset in Fig. 4. Although there are a limited number of papers (<15) on magnetic and electric field assisted hydrothermal synthesis, the number of publications on microwave assisted hydrothermal synthesis exceeds 115 in 2019 alone. Similar to the publication numbers of papers, 141 patents on microwave assisted hydrothermal synthesis, 37 patents on continuous hydrothermal synthesis, 9 patents on magnetic field assisted, 1 patent on electric field assisted hydrothermal synthesis have been published since 2000. Consequently, large numbers of published papers and patents on hybrid hydrothermal synthesis have been issued by companies and scientists to improve both powder properties and process efficiency.

Table 1 Particle characteristics depending on the powder synthesis methods

Powder Synthesis methods	Size	Morphology control	Stoichiometry	Purity	Aggregation
Solid-state reaction (mixed-oxide)	Coarse (micron)	Poor	Poor	Low	Yes
Coprecipitation	Coarse (submicron–micron)	Medium	Good	Medium	Yes
Sol–gel	Fine (nanosubmicron)	Medium	Good	High	Yes
Molten flux	Coarse (micron)	Medium	Medium	Low	No
Vapor phase	Fine (nanomicon)	Medium	Poor	High	Yes
Hydrothermal	Fine (nanosubmicron)	Good	Good	High	No

**Fig. 3** The hydrothermal synthesis tree, which shows branches of hydrothermal synthesis reported in the literature to date.

Among these hybrid hydrothermal methods, the microwave assisted hydrothermal synthesis has had high research interest in recent years. Compared with the traditional hydrothermal method that performed in relatively high reaction temperature differences and long reaction time, the microwave hydrothermal method gives ultrafine nanoparticles with narrow particle size distribution and uniform morphology by applying a fast and uniform heating system. Recently, hydrothermal powder synthesis and its applications for smart materials were reviewed by [Shandilya *et al.* \(2016\)](#) where they focused on process definitions, technological merits, and current applications. In another study, [Yang and Park \(2019\)](#) reviewed the developments on the conventional and microwave hydrothermal methods, their reaction mechanisms, and practical applications of the two methods.

General Principles and Equipment

In hydrothermal synthesis, chemical reactions of substances take place in a sealed and heated aqueous solution at elevated temperatures ($T > 25^{\circ}\text{C}$) and pressures ($P > 100 \text{ kPa}$) to form crystalline materials directly from solution. In this method, pressures as high as 500 MPa and temperatures up to 1000°C can be utilized to enhance dissolution of reactants and subsequently the nucleation and growth of certain types of materials such as single crystals of oxides, diamond, or carbon nanotubes ([Suchanek *et al.*, 2004](#)). If the

Fig. 4 The number of publications on hydrothermal synthesis for each year beginning in 2000. The data were collected from the Web of Science by using key words *hydrothermal* and *synthesis*.

synthesis takes place in a nonaqueous solution with organic solvents at relatively high temperature, it is called solvothermal synthesis. There are different forms of solvothermal synthesis based on the solvent type, such as alcohols, glycols (i.e., ethylene glycol, diethylene glycol, triethylene glycol) or oleylamine (OAm). For example, the solvothermal method is called glycolthermal synthesis when glycols such as ethylene glycol or 1,4-butanediol are used as solvents (Adair and Suvaci, 2001) whereas it is called alcohothermal synthesis when alcohols (e.g., ethanol) are used.

In hydrothermal and solvothermal systems, sealed container (reactor or autoclave) or high-pressure autoclave is used under subcritical or supercritical conditions of the solvent. The pressure developed in an autoclave is related with the filling volume (typically maximum filling volume is 70% of the autoclave capacity to assure the process safety). In most cases, reactors are metal autoclaves such as stainless steel or high-strength alloys with Teflon or alloy linings. Teflon inserts are commonly used in autoclaves up to 200°C and 20 MPa synthesis conditions because they are inert to both acidic and alkaline media compared with glass and quartz inserts. In the case of Teflon uses at $T > 200^{\circ}\text{C}$, Teflon can creep and this can cause undesired problems. In such cases, other alternative materials such as high-strength alloy autoclaves with tubes made from platinum, gold, or silver are utilized to protect the autoclave body from the corrosive solvents or ingredients (Li et al., 2015).

Approaches for Hydrothermal Synthesis

There are several steps that should be considered for achieving desired powder characteristics in hydrothermal synthesis process. The algorithm for a hydrothermal synthesis shown in Fig. 5 demonstrates a general perspective for hydrothermal synthesis application to achieve target material properties.

What is the Nature of the Material?

Before starting synthesis of any materials, the nature of the materials to be synthesized should be known and their expected properties should be identified or listed. It is essential to understand the materials properties to optimize or control their particle features. Material properties can be classified as chemical properties, physical properties, colloidal properties, electronic properties, and optical properties (Adair et al., 1988, 1998). The critical chemical properties such as phase equilibria and solubility are necessary to control phase purity. The physical properties such as crystal structure and equilibrium crystal shape, dictated by surface energies of crystallographic plane, are important to control the morphology of particles. The colloidal properties include surface groups, hydrophilicity, isoelectric point, Hamaker constant, etc., and they are useful to control to dispersion of particles in solutions or preventing agglomeration of particles. Since the attractive van der Waals forces among the particles result in agglomerated particles, they can also affect electrical properties (e.g., dielectric constant, dielectric dispersion, ferroelectricity, piezoelectricity, ferromagnetism) and optical properties (e.g., band gap, absorption spectra) (Adair et al., 1988, 1998).

Fig. 5 Algorithm for a hydrothermal synthesis.

What are the Expected Powder Characteristics?

The powder characteristics that can control properties and performances of particulate materials are stoichiometry, phase stability, size, size distribution, morphology, purity, and degree of agglomeration. To establish phase stability, combinatorial routes for phase development can be applied, dissolution and phase changes are evaluated, and process variables such as degree of supersaturation, solution pH, and temperature should be employed. The control over size of the particles can be achieved by degree of supersaturation control, nuclei concentration, homogeneity of solution, and solution properties such as viscosity, ionic strength, etc., as described in the mechanism section below. In the case of the morphological control for particles, surface equilibria, complexing agent, and surface electrostatic features play important role during hydrothermal synthesis. To prevent aggregation, surface charge of particles must be controlled and interaction energies, van der Waals and polarization forces and organic adsorbates should be considered (Adair *et al.*, 1988, 1998).

The hydrothermal method allows controlling of material characteristics with stoichiometry. Therefore, this method is often chosen to synthesize or produce different types of nanomaterials such as silicates, zeolites, oxides, ceramics, metals, alloys, composites, and so on. These materials can be in variety of forms such as equiaxed (e.g., cubes, spherical), elongated (fibers, whiskers, nanorods, nanotubes), plates, etc., as shown in Fig. 1. With hydrothermal synthesis, particle size and morphology characteristics can be manipulated over a wide range. For example, whiskers, plates, or cubes can be oriented to form materials with single crystallite like properties, such as textured ceramic-ceramic composites with anisotropic properties (Suchanek and Riman, 2006). Recently, much effort has been devoted to improve physical, chemical, and electrical properties of nanomaterials by designing of these material characteristics. For example, as anode material, Zn_2SnO_4 particles with high purity, smaller particle size, and uniform morphology have the best properties for Li ion batteries. With improving physical properties and morphological structures of Zn_2SnO_4 materials, battery performance and the electrochemical performance can be enhanced with hollow cube structure compared with dispersed single crystal cubes (Zhao *et al.*, 2016).

Surface and Colloid Chemistry of the Material in Aqueous Media

Water is an environmentally safe material and cheaper than other organic solvents and thus it is much more widely utilized in hydrothermal synthesis compared with organic solvents. Frank (1978) summarized the physical and chemical properties of water dependent pressure and temperature (PT) data under hydrothermal conditions. These data and other physical properties for water up to 1000°C and 1000 MPa are well known (Byrappa and Yoshimura, 2001). Under high temperature and pressure conditions in an autoclave, the density, surface tension, and viscosity of water will be lower resulting in significantly higher ionic and molecular mobility than at ambient conditions (Feng and Li, 2017). Therefore, since solvent properties of water under high temperature and pressure can be considerably changed, using of pressure and temperature diagram of the water effectively is very important for understanding the hydrothermal synthesis better. Because of the increased ionization of water caused by increased temperature, the ionic or chemical reactions of the indissoluble inorganic materials can be promoted under hydrothermal condition at the high temperature and pressure.

Another important issue of hydrothermal synthesis is to understand the surface and colloid chemistry of materials in an aqueous reaction medium. When metal oxide based powders are immersed into water, surface charge develops on the particles. The most important charging mechanism for these systems are (1) the dissociation of the surface to yield an ion (usually a proton) to the solution; (2) Nernstian charging through specific adsorption or desorption of lattice ions; (3) metal hydrolysis via ionization of the

particle surface due to protonation or deprotonation of acid or basic surface groups; and (4) incongruent dissolution (leaching). Mechanism 3 is commonly observed for all metal oxides (except silica) and metal hydroxides. Solution pH is the most critical solution feature, which can be used to change surface charge. Mechanism 4 involves metal hydrolysis with incongruent dissolution of the at least one of the cationic species (Adair *et al.*, 2001). Especially, final mechanism is critical to mixed metal (multication) oxide systems. Therefore, during in situ transformation of powder from precursor solution or precipitation–recrystallization in aqueous media, cation concentration must be under control to conserve stoichiometry of each component because of the such colloidal interactions between particles and water molecules. This has been shown by Tuncolu *et al.* (2015) where excessive Zn^{2+} dissolution during washing of the precipitated Zn_2SnO_4 phase results in difficulty in stoichiometry control.

Evaluation of the Solubility–pH Diagrams in Aqueous System

Evaluation of the solubility–pH diagram is another important issue for understanding dissolution–reprecipitation behavior of metal salts depending on concentration, pH of solution, and temperature. When suspended particles dissolve into solution, they supersaturate the solution and then dissolution–recrystallization is observed and consequently particles precipitate in the solution. Solubility limits of starting metal oxide salts and solubility behavior of materials will change depending on pH and concentration in reaction solution and subsequently they will affect. Thus, assessment of the solubility–pH diagram will help to choose appropriate initial concentration of cations and pH of the reaction medium. For example, Since Zn^{2+} solubility is greater than Sn^{4+} solubility; in our earlier studies, to achieve stoichiometric Zn_2SnO_4 particles, excess Zn^{2+} (i.e., $\text{Zn}^{2+}/\text{Sn}^{4+} = 2.4$ instead of $\text{Zn}^{2+}/\text{Sn}^{4+} = 2.0$) should have been added to system prior to hydrothermal synthesis at pH 8.0 (Tuncolu *et al.*, 2015). In the case of the limiting solubility in water, mineralizers such as pH adjusting agents (e.g., acids or bases) or the complexing agents can be added to enhance the solubility in water. When starting materials have higher solubility and difficulties in the control of dissolution–recrystallization in aqueous media, solvothermal synthesis can be considered with organic solvents. On the other hand, in hydrothermal synthesis, some materials such as barium titanate or hydroxyapatite often can exhibit water related lattice defects or poor stoichiometry. For example, in barium titanate synthesis, hydroxyl ions substituted for oxygen ions generate barium ion vacancies, which degrade the dielectric properties; in hydroxyapatite synthesis, poor control of its calcium stoichiometry can be observed at presence of residual water (Suchanek *et al.*, 2004). In such cases, the problem of water incorporation can be overcome by either adjusting synthesis conditions or by using of solvothermal processing with nonaqueous solvents.

What are the Thermodynamics and Kinetic Variables for the Hydrothermal Synthesis?

Thermodynamics and kinetic variables are the key parameters that control the hydrothermal synthesis and hence final product characteristics. Therefore, these variables should be evaluated for the materials system in detail prior to hydrothermal synthesis. The thermodynamic process variables are concentration of reactants and additives, temperature and pH of solution (Suchanek and Riman, 2006). These parameters influence both reactor and crystallization kinetics. Crystal morphology and size can be modified by surfactants that can adsorb on specific crystallographic faces (Ring, 1996). Size of the crystals and phase purity can be controlled by varying temperature and concentration (Tuncolu *et al.*, 2015). Mass transport process and kinetics of chemical reactions generally increase in magnitude with increasing temperature. Mass transport process and chemical reaction rates generally increase in magnitude with increasing temperature. Since the kinematic viscosity for hydrothermal solution is approximately one order of magnitude lower in aqueous media than that for the gas phase. As a result, the hydrothermal synthesis conditions allow fast transport and high dissolution rates. Since the effect of pressure on the viscosity is significant only above the critical points of temperature and pressure, mass transport process and chemical reaction rates do not change with pressure during typical hydrothermal synthesis where usually temperature and pressure are below the critical values. The influence of pressure on the process is observed when the pressures exceeds 100 MPa and only at $T > 300^\circ\text{C}$ (Suchanek and Riman, 2012).

If the thermodynamic variables are limited to achieve the desired morphology and size control, nonthermodynamic variables such as stirring can be employed to enhance uniformity and the control over the particle formation process. Previous studies showed that the stirring speed can be varied to change morphology of the particles during the hydrothermal synthesis. Potential segregation problems that can be caused by concentration and temperature gradients or low heating rates can be prevented by stirring (Suchanek and Riman, 2012).

Powder Synthesis via Hydrothermal Method

In practice, a typical powder synthesis via hydrothermal method usually involves four important stages including selection of precursor, precipitation and gel formation, removal of undesired species, and hydrothermal reactions. Fig. 6 shows the steps of hydrothermal synthesis as a flow chart.

Selection of Precursors

In hydrothermal synthesis, many types of precursor such as aqueous solution of dissolved salts, aqueous dispersion of solids (suspensions), or precipitated colloidal dispersion (gel precursors) are used. Metal salts such as nitrates, chlorides, sulfates,

Fig. 6 Stages of the hydrothermal synthesis.

acetates, etc., have solubility in aqueous media and are generally used as a starting material. Inexpensive precursor compounds, easy to handle chemicals, and compounds that react cleanly to form the product are desired. When choosing metal salts as a starting material, the role of released ions on the purity, size, and morphology of synthesized powders should be considered. Detailed recommended features for different type of precursors to provide reasonable yields of product were already reported in previous studies (Adair *et al.*, 1988, 1998). In one of the earlier studies, the effect of the precursor type on the morphology of the hydrothermally synthesized ZnO particles was evaluated by using ZnCl_2 and $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ precursors (Ozel *et al.*, 2016). It has been shown that during hydrothermal synthesis of ZnO particles, particle size and morphology of ZnO crystals were affected from precursor type and initial concentration that result in change in growth mechanisms such as classical nucleation growth or Ostwald ripening. When ZnCl_2 was used as precursor, agglomerated ellipsoidal rod like morphology was formed with classical nucleation growth mechanism whereas flower like morphology was obtained by using $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ precursor via Ostwald ripening for the initial concentration range between 0.25 and 1 M.

Preparation of Gels

In addition to solutions and dispersions, precipitated intermediate forms such as gels or sols are frequently used as precursors in hydrothermal synthesis. Gel formation can be achieved by either homogeneous precipitation or direct strike precipitation methods. In the homogeneous precipitation technique, the precipitation occurs homogeneously due to uniform pH change in the solution, where homogeneous precipitation agents such as urea and hexamethylenetetramine are activated by heating or using enzymes. On the other hand, in the direct strike precipitation method, direct addition of acids or bases into the solution results in precipitation. Since the pH change in the solution is much more uniform, the gel structure is usually more homogeneous in the homogeneous precipitation with respect to that of the direct strike precipitation. However, the direct strike precipitation is readily applicable and can be used at high molarity levels while the homogeneous precipitation is only suitable at relatively low concentrations.

Removal of Undesired Species

In hydrothermal synthesis, the chemical purity of the powder materials is higher due to starting with high purity precursors. During crystallization processes, growing crystals/crystallites tend to reject impurities present in the growth environment. Therefore, it is expected that impurities such as ions come from metal salts or pH adjusting agents remove from the system together with

the crystallization solution. However, some of them can be adsorbed to particle surface due to the colloidal interactions between particles and present ions. If high purity in the synthesis powder is the target to obtain excellent physical properties and high material performance, two steps hydrothermal synthesis must be considered to removing of undesired species comes from metal salts by washing with pH adjusted water rather than using one step hydrothermal synthesis that involves direct feeding of the gel prepared above and its supernatant to the autoclave without separating the gel and supernatant (Tuncolu *et al.*, 2015). For example, high purity Zn_2SnO_4 powder via hydrothermal method was synthesized by removing anions with pH adjusted water to obtain better ceramic target performance to develop thin film for transistor channels.

Additives

The varieties of synthesis precursors, mineralizers, and additives such as organics, complexing agents, surfactants, or adsorbates offer more room for design the material characteristics. Mineralizers are either inorganic or organic additives and are often used to adjust pH and improve solubility. In addition, there are other additives that are used to promote particle dispersion or control crystal morphology. Complexing agents can establish morphological control for particles. Surfactants and organic adsorbates prevent aggregation of particles (Adair *et al.*, 1988, 1998). Recently, in a review article, Shi *et al.* (2013) demonstrated utilization of four hydrothermal synthesis approaches (i.e., organic additive-assisted, organic additive and template free, template assisted, and substrate assisted hydrothermal syntheses) to control particle size and morphology effectively during the hydrothermal synthesis of inorganic semiconducting nanoparticles.

Mechanisms

Powder synthesis during hydrothermal process involves utilization of precursors. Such precursors can be sols, gels, or suspensions. Conversion of such precursors to powder can occur via either in situ transformation or dissolution-precipitation mechanisms. In the former, characteristics of the precursor can dictate the powder characteristics, whereas, in the latter mechanism, precursor is completely dissolved and then precipitates in powder form. Therefore, precursor characteristics are not transferred directly to the powder during this mechanism. It should also be noted that as mentioned above regardless of mechanisms, powder formation can still be kinetically controlled by chemical characteristics of the precursor such as ion release rate, formation of less soluble intermediate phases, etc. Besides precursor type and concentration, the morphology of the ZnO crystals is also influenced by pH of the solution and used alkaline solutions such as KOH, NaOH, or NH_4OH . For example, Podlogar *et al.* (2016) showed that the resulting morphology of the ZnO with different shapes and crystal sizes can be achieved by altering the pH of the suspension with NaOH solution after the precipitation. Depending on the ratio of $\text{Zn}^{2+}/\text{OH}^-$ ions in the starting solutions, rods or branched clusters composed of rod-like crystals were observed after the hydrothermal treatment of pure $\text{Zn}(\text{OH})_2$ at the highest ratio of $\text{Zn}^{2+}/\text{OH}^-$ ions of 2.5 whereas petal-like ZnO crystals precipitated from the solution and only coarsened at the expense of dissolved $\text{Zn}(\text{OH})_2$ by lowering the $\text{Zn}^{2+}/\text{OH}^-$ ion concentration and sphalerites-like ZnO precipitated at the lowest $\text{Zn}^{2+}/\text{OH}^-$ ratio of 0.1.

Final powder characteristics, particularly size and morphology, are directly determined by nucleation and growth kinetics during hydrothermal synthesis. According to the classical nucleation and growth theory, as cation concentration increases number of nuclei increases due to higher saturation and nucleation frequency and hence particle size decreases. However, if some of the nuclei are too small to survive, they dissolve and increase the saturation level so that other relatively larger nuclei grow at the expense of those fine nuclei. Such growth process is called Ostwald ripening. In such systems, particle size increases as cation concentration increases. It has been shown that there is a critical cation concentration (CCC) for the hydrothermal systems at which nucleation and growth mechanism changes. While the mechanism described by Ostwald ripening is effective at concentrations below the CCC, classical nucleation and growth theory is effective at concentrations greater than the CCC (Fig. 7). The CCC is a function of temperature, pH, pressure, concentrations of other ions and all other processing parameters that can affect solubility of the powder constituents in particular cations. Aciksari *et al.* (2016) showed that for hydrothermal synthesis of SnO_2 , the CCC was 0.1 M.

The growth process determines the final particle size during hydrothermal synthesis. The growth rate is controlled by either diffusion or interface reaction. The growth mechanism can be determined by using LSW (Lifshitz, Slyozov, and Wagner) theory where

$$r^n - r_0^n = kt$$

where, r is the average particle size at time t ; r_0 is the average initial particle radius; k is rate constant; t is the allowed time for the growth; and n is the constant describing the mechanism. If $n = 2$, the growth is controlled by interface reaction whereas if $n = 3$ then diffusion is the rate controlling mechanism. Since determination of the mechanism enables one to tailor the processing parameters to achieve the targeted particle characteristics, such understanding can also enhance the predictability of the final powder characteristics.

Modeling

Like all well-developed industrial processes, to make hydrothermal synthesis one of the most preferred and widely used powder synthesis methods by the industry, it should be possible to predict the product and its characteristics as a function of critical

Fig. 7 Effect of the initial cation concentration on the growth mechanism during the hydrothermal systems.

processing parameters without requiring many trial and error type experiments. This can only be achieved by modeling hydrothermal processes where thermodynamic and kinetic effects play critical roles on the powder characteristics. Therefore, many researchers have involved in modeling hydrothermal synthesis so that it will be one of the mainstream particle synthesis technologies.

In early attempts, hydrothermal synthesis was modeled based on the thermodynamic criteria for ideal solutions to predict phase stability diagrams for the systems under investigation (Baes and Mesmer, 1976; Adair *et al.*, 1988, 1998). However, since the precursor concentrations and corresponding powder yields are not specified by such phase stability diagrams, it was proposed to use of yield diagrams that demonstrate specific synthesis conditions to achieve precipitation of the phase of interest, quantitatively (Lencka and Riman, 1993). Phase stability and yield diagrams are calculated based on a thermodynamic model that follows the Helgeson–Kirkham–Flowers–Tanger equation. This equation uses activity coefficients to predict standard state properties of aqueous species with a nonideal solution model. Methodology for generating phase stability and yield diagrams was discussed by Suchanek *et al.* (2004) in an earlier publication.

Although thermodynamically derived phase stability and yield diagrams are very critical to understand the roles of concentration, temperature, and pressure on the final phase, as well as effects of precursor type on final powder characteristics and the cost, there are other phenomena such as hydrothermal reaction rate, particle size, and morphology development that are controlled by kinetic factors. Therefore, in addition to thermodynamic modeling, kinetic models that can predict the reaction rate, particle size, and morphology should be developed. Although the thermodynamic models are mature and their high prediction capability for some specific systems has been successfully shown, the kinetic models are not mature enough yet and hence they still need to be improved. Accordingly, to engineer hydrothermal reactions after the phase stability and the yield diagrams are established for the materials of interest, hydrothermal experiments should be designed to test and validate the calculated diagrams and after the validation experiments the processing variable-phase maps can be generated and they can be used to predict hydrothermal reaction and crystallization kinetics (Suchanek and Riman, 2012).

Ultrasonic Sprayed Aerosol for Ultrafine Ceramic Powder Synthesis

Sylvie Foucaud, University of Limoges, Limoges, France

Introduction

The control of the final ceramic microstructure depends strongly on the characteristics of starting powders like chemical composition and particle size distribution. To favor the multi-functional ceramics rise, development of new composite powders with high chemical purity and controlled particle size distribution is necessary. For areas such as biomedical, electronics, catalysis, energy storage etc., the morphology of the powder should be designed with different properties in the core or at the surface of the grain. In this case, the synthesis processes must be able to lead to original architectures such as core-shell structures.

To reach high chemical purity and ultrafine particle size, numerous dedicated synthesis methods have been developed. These processes can be classified into three categories (Ring, 1996): solid, liquid and gaseous routes. In the case of solid phase reaction synthesis, three types of chemical reaction are referenced; oxidation or reduction of a solid, thermal decomposition of a solid, and solid state reaction between two types of solid, and in particular, mechanical alloying methods. Gaseous phase ceramic powder synthesis routes consist in evaporation-condensation and chemical reactions in the gas phase. Concerning liquid phase synthesis, six different methods can be cited: drying of a liquid, precipitation, reactions of a liquid metal melt with a gas, hydrothermal treatment, sol-gel synthesis (for synthesis of oxide ceramics), and Polymer Derived Ceramics route (PDC, for non-oxide ceramics). Solid state syntheses of ceramic powders are known for the difficulty to obtain in the same time pure powders without residual species and ultrafine particle size. For gas phase synthesis, the major disadvantage lies in the use of expensive and sometimes dangerous gaseous species. Moreover, for some materials it is not always possible to find a gaseous precursor, which narrows the range of achievable compositions.

Liquid routes allow overcoming these drawbacks: there is a huge number of available precursors, whether they are liquids themselves or they consist in a solution (salts, organometallics). Liquid phase mixing ensures the homogeneity of the precursor media, and as most liquid processes do not induce pollution, the purity of final products is generally the consequence of the initial purity of the precursors. Dedicated precursors can also be synthesized by chemical engineering: the PDC or sol-gel routes rely on the synthesis of organometallic precursors (sol or polymer), with accurate composition and viscosity, which are then heat-treated to form oxide or non-oxide ceramics with tunable properties according to the operating conditions (synthesis and/or thermal treatment). Furthermore, the possibility to obtain multi-element powders and original architectures such as core-shell structures by liquid state processes paves the way to the development of novel materials with tailored original properties. Beyond powders, the versatility of PDC and sol-gel routes has been demonstrated through numerous investigations showing their ability to synthesize films, fibers, monoliths and composites.

The direct thermal treatment (pyrolysis) of the liquid precursor cannot lead to a homogenous and ultrafine powder. To maintain the initial homogeneity of the precursor mixture in the final product, and to obtain small particles, the liquid phase has to be divided in small droplets that can be further heat treated separately (the droplet is the reactor) or vaporized (similarly to gas phase processes). In this context, the spray pyrolysis process, also called aerosol decomposition, is a technique in which a precursor solution (e.g., salt or mixed salts solution, organometallics, liquid polymers, colloidal suspension) is dispersed, via an atomizer or a nebulizer, into fine droplets (aerosol), which further undergo in-flight thermal treatment and experience physical/chemical phenomena including evaporation, precipitation, drying, thermolysis or decomposition into inorganic phases (oxides or non-oxides), sometimes in-flight sintering, to produce ultrafine or nanometric powders in one single step. The resulting solid particles form a dry aerosol carried by the process gas to collectors downstream where filters can separate the powders from the gaseous phase. These powders can then be collected directly in dry route, or solvent can be added in order to form a slurry for nanoparticles safety issues. These flow processes operate continuously and are very suitable for upscaling to industrial level. Some of them are already used to produce tons of materials per year (Ulrich, 1984; Gutsch *et al.*, 2002). Laboratory-scale processes can easily produce several tens of grams per hour of nanopowders.

Spray pyrolysis processes, also called aerosol-assisted vapor phase syntheses, are known to lead to powder grain size lower than 1 μm as it was demonstrated for TiO_2 , Al_2O_3 , TaC or GaN for example (Janik *et al.*, 2006; Baseta and Biscans, 2007; Cheng *et al.*, 2017). Spray pyrolysis processes differ in the energy source used for the in-flight thermal treatment step of the aerosol. The most used ones are the combustion flame and the furnace, secondarily the laser and the plasma (Baseta and Biscans, 2007; Cauchetier *et al.*, 1991). Fewer studies are also devoted to microwave assisted spray pyrolysis (Li *et al.*, 2016). The ceramization behavior of many precursors was studied intensively for each experimental set-up aiming to a detailed description of the chemical reactions involved. However, the comparison between the different methods is difficult because most often, different sets of precursors were used when different techniques were applied.

The combustion flame (flame spray pyrolysis process) is very widely used for oxide nanoparticles synthesis, even if this process can be used for metallic nanoparticles as well (Athanassiou *et al.*, 2010). Most of the time the spray is generated by pneumatic nebulizer rather than with ultrasonic device and this process is very rarely used for non-oxide ceramics. Several interesting review

Fig. 1 Principle of operation of different methods of nebulization. Reproduced from Le Moyne, L., 2010. Atomization, Pulvérisation et Aérosols. Techniques Ingénieur.

papers can be found in the literature (Strobel and Pratsinis, 2007; Teoh *et al.*, 2010). Plasma source can be operated at very high temperatures that enable the use of cheap solid precursors. The liquid route, though existing (Arita *et al.*, 2017), is thus less extensively documented in the literature where most of papers dedicated to nanopowders synthesis deal with inductively coupled plasma torch used to vaporize raw powders furtherly condensed into nanoparticles (Leparoux *et al.*, 2005). Furnace (thermal spray pyrolysis) and laser (laser spray pyrolysis) processes, operating at lower temperatures and/or with shorter residence times, are more suitable to highlight the use of ultrasonic generated aerosol because they take advantage of the small droplet size. Thus these two processes were chosen to be presented in this paper.

Nebulization Techniques

Aerosol Generation

In the spray pyrolysis process, different atomization systems can be used. One of the best known is the pneumatic nebulization which consists in destabilizing the liquid jet with a flow of gas under pressure (Fig. 1(a)), thus forming droplets. In the ultrasonic nebulization process, the aerosol results from the vibrations imparted to a liquid layer by a piezoelectric material (Fig. 1(b)): the waves formed by this vibration become unstable and produce the ejection of drops. Finally, the electrostatic nebulization (Fig. 1(c)) consists in applying a constant electric field to a jet of liquid so as to reduce the effective surface tension of the liquid and cause the detachment of the drops. These methods differ in the size distribution of the drops formed, the rate at which the drops are ejected from the liquid volume and the nebulization rate (Messing *et al.*, 1993).

One of the main disadvantages of atomizing a liquid by conventional means such as pneumatic atomization is the difficulty to obtain narrow droplet size distributions. In many case, when large droplets issues is critical, a cyclone has to be used at the outlet of the nebulizer to cut the larger part of the size distribution. The consequence is a decrease in production rate. The other drawback of pneumatic nebulizer is the resulting carrier gas flow. Indeed, the inlet gas pressure cannot be decreased too low as the gas is the driving force for nebulization. Such high carrier gas flow rates induce shorter residence time in the reaction zone, which can impede the precursor decomposition yield in fast processes as laser spray pyrolysis for example. On the other hand, ultrasonic nebulization appears as an alternative for the production of very small drops which size can be tuned by adapting mainly the ultrasound frequency. These generators produce generally narrower size distributions (Mwakikunga, 2014; Barba *et al.*, 2009; Blandenet *et al.*, 1981). As the aerosol is produced by the piezoelectric transducer, the carrier gas flow can be tuned independently from the droplet production rate, and thus can be set to lower values when compared to pneumatic nebulization. Finally electrostatic nebulization consists of applying a constant electric field to a liquid jet and causing the production of drops. This latter process is rarely used for powders synthesis and thus will not be detailed here.

In the case of ultrasonic nebulization, ultrasound waves are applied to a film or a volume of liquid by a piezoelectric actuator in order to cause liquid fragmentation into fine droplets. The formation of a spray from a liquid by ultrasound waves is supposed to be caused by two principal mechanisms: the capillary wave instability development at the liquid surface and the cavitation phenomenon. The droplet formation due to capillary waves is based on Taylor's instability theory which explains the instability apparition and development at the interface between two fluids with different densities: this phenomenon appears at relatively low frequency of ultrasound (20–100 kHz) and is identified by the formation of a well-structured wave pattern on the liquid surface, observed by some authors (Lang, 1962; Yule and Al-Suleimani, 2000; Avvaru *et al.*, 2006; Ramisetty *et al.*, 2013). The waves produce drops from the ejection of their peaks when they are destabilized (Rajan and Pandit, 2001). The cavitation phenomenon appears at higher frequencies (0.1–5 MHz), and is caused by local changes in pressure, due to high frequency waves through the liquid, that forms vapor cavities in the liquid volume until their implosion causes liquid rupture with droplet ejection (Franc and Michel, 2004).

Modelization

To understand the spray pyrolysis process, the understanding of each step is important and in particular, the relationship between the size distribution of the aerosol produced by the nebulizer device and the synthesized powder characteristics. The first step of the spray pyrolysis process is the generation of the used liquid precursor aerosol. This step consists in ultrasonic nebulization of a volume of liquid, forming a mist which is then transported by a gas to the pyrolysis reactor. The size of the drops that constitute the fog varies depending on the characteristics of the liquid to be sprayed, including its viscosity and surface tension, and the frequency and power of the ultrasound delivered by the generator. The aerosol droplet size distributions can be estimated experimentally with a shadowgraph imaging device. All size distributions show a bimodal shape (around 3 and 9 μm) that evolves between the different measurements locations, but remains present until the reactor entrance.

An empiric modeling of the mean particle diameter depending on the precursor physical properties and nebulizer device can then be carried out by adapting correlations laws proposed in the literature to the specific device and liquids used in the study of Munoz *et al.* (2018). It allowed defining an initial state of the precursor before entering in the reaction zone corresponding to the decomposition and recombination steps, establishing a clearer relationship between the aerosol and final powders characteristics and contributing to understand the mechanisms involved in the process.

To improve the agreement of the average diameter obtained by correlation laws with experimental values, dimensionless numbers have been adapted to the system and used to obtain the coefficients for the proposed correlation. The Ohnesorge number was considered in its original expression (noted Oh' , Eq. (1)). The Weber number (noted We') and the intensity number (noted In') were also reformulated (Eqs. (2) and (4)) including parameters like the thickness and volume of liquid and the power applied to the aerosol generator:

$$Oh' = \frac{\eta}{(\rho \sigma e)^{\frac{1}{2}}} \quad (1)$$

$$We' = \frac{\rho A m^2 f^2 e}{\sigma} \quad (2)$$

$$In' = \frac{P}{\rho V A m^2 f^3} \quad (3)$$

where e is the liquid thickness (m), P the power applied to the aerosol generator (W), V the liquid volume (m^3), λ the wavelength (m), σ the surface tension (N m^{-1}), ρ the density (kg m^{-3}), f the ultrasound frequency f (s^{-1}), η the viscosity of the liquid (Pa s), $A m$ the amplitude of the surface waves (m).

The selected dimensionless numbers expressions were then used to calculate the new exponents of the correlation law still considering the structure of Avvaru's one. The obtained expression is shown in Eq. (4).

$$d = 1.2765 \left[\left(\frac{\pi \sigma}{\rho f^2} \right)^{\frac{1}{3}} + 9.48 \exp^{-7} (We')^{0.347} (Oh')^{0.435} (In')^{-1.65} \right] \quad (4)$$

Observing both terms of the expression 4 separately, the first one, that only considers the term of capillary waves, describes the bigger drops population. The second one, that represents the cavitation term through the association of dimensionless numbers, describes the smaller population of the bimodal distribution of formed droplets. This equation is valid for density ranging between 774 and 998 kg m^{-3} , the surface tension between 0.018 and 0.073 mN m^{-1} and the viscosity in the range 0.62–1.2 mPa s .

The curves of droplets size distribution obtained in this part of the study (evaporation, drops-wall interaction, coalescence) are shown in Fig. 2. Its comparison to experimental results in three positions of measure was also traced. The experimental evolution of drops size distributions for the liquid shows a slight variation between three positions of measure, result that is reproduced by simulated curves. Otherwise, the width of distributions matches between experimental and simulated results and different populations of drops are well identified in both cases.

Description of a Generic Spray Pyrolysis Set-Up

The generic set-up detailed in this part was developed in order to work under inert or reactive atmosphere to reach non-oxide or oxide compositions. This process can be divided into three main parts (Fig. 3):

- (1) Precursor aerosol generation,
- (2) Conversion of the precursor into ceramic (pyrolysis),
- (3) Powders collection (filtration).

Aerosol Generator Device

The generator used is composed of a glass chamber seated on a metallic support containing an ultrasonic transducer. A water circulation between the transducer and a plastic membrane allows regulating the temperature of the precursor solution filled over the membrane, especially to ensure the reproducibility of the experiments since the surface tension and the viscosity of liquids

Fig. 2 Drop size distributions considering all phenomena and compared to experimental results in each position of measure.

Fig. 3 Schematic representation of spray pyrolysis process.

strongly evolve with the temperature. The transducer is a barium titanate ceramic. The frequency and power alimentations are in the order of a few hundred kHz and in the 0–170 W range respectively. These values have to be adjusted according to the precursor rheological properties and to the required precursor feeding rate. There are many commercially available aerosol generators with different operating frequencies and powers. The continuous precursor feeding is controlled by a peristaltic pump to keep the liquid level constant into the aerosol chamber. The aerosol chamber is directly connected to the pyrolysis set-up. Once the aerosol formed at the surface of the liquid, it can be carried to the reaction chamber by a neutral or reactive gas flow. This carrier gas flow rate as well as ultrasound power enables the control of the precursor feeding rate.

Pyrolysis Set-Up

As discussed before, two different pyrolysis techniques are preferred, namely thermal spray pyrolysis (using a furnace as energy source for the reaction) and laser spray pyrolysis (using a laser as energy source).

The thermal spray pyrolysis process (Zhang *et al.*, 1990; Song *et al.*, 2004; Salles *et al.*, 2007) is a versatile and simple method for the production of oxide powders and also adaptable to the production of non-oxide powders. Almost any kind of liquid precursor can be

Table 1 Comparison between laser and furnace pyrolysis

	Laser Pyrolysis	Furnace Pyrolysis
Source of energy	CO ₂ laser	Furnace
Temperature control	500–2000°C ^a	800–1500°C
Residence time of the species in the reaction zone	<70 ms	Between 0.5 and 1.5 s

^aThe temperature is not regulated but results from the absorption of the beam by the reaction medium.

used, as long as it can be nebulized. The basic principle is the evaporation/reaction of the aerosol liquid droplets by in-flight heat treatment in an oven, aiming at the formation of ceramic powders through different phenomena that will be described in the next section.

In a conventional thermal spray pyrolysis set-up, the furnace consists in a ceramic tube where the precursor solution can be sprayed with a neutral or reactive carrier gas. The precursor micro-droplets are mainly heated by radiation transfers from the walls (Salles *et al.*, 2007). Typical reaction temperatures are in the 800–1500°C range, with residence time in the order of magnitude of 1 s depending on the carrier gas flow and the length of the isothermal zone of the furnace.

The Laser spray pyrolysis process (Cannon *et al.*, 1982; Cauchetier *et al.*, 1987) is based on the interaction between a CO₂ laser beam emitting at 10.6 µm and the precursor, or with a sensitizer when the precursor does not absorb the laser wavelength itself. Because of the low-energy photons, there is no photodissociation but the temperature upon absorption raises high enough to decompose the molecules: it is actually a pyrolysis effect. This process can be seen as very versatile, but its efficiency strongly depends on the precursor. When this latter does not absorb the laser, which is the case for the majority of materials, a sensitizer such as NH₃, C₂H₄ or SF₆ has to be added, leading to low decomposition yield and possible powder contamination. Moreover, the short residence time, which is an advantage when small nanoparticles are wanted, requires small droplets in the aerosol to ensure complete precursor decomposition. In that case ultrasonic aerosol generator is almost mandatory, and as will be discussed in the aerosol generation section, this means low concentration solutions for precursors and thus low production rates. For example, production rate at the lab scale for SiC nanopowders can easily reach several tens of grams per hour because the precursors are gaseous and at least one of them (SiH₄) absorbs directly the laser radiation. On the opposite, some compositions requiring liquid media with low solubility of the salts hardly reach few hundreds of milligrams per hour.

Despite of these drawbacks, laser pyrolysis enables an accurate control over the nanoparticles size under 10 nm and over the crystallinity of the materials. Residence time for the precursor is indeed very short due to the limited interaction region with the beam. This latter can be focused to decrease the interaction zone dimension down to a few µm, leading to residence times as short as few milliseconds. This residence time can also be tuned through total gas flow rate and aerosol inlet nozzle diameter. Moreover, the laser can be operated continuously (aiming at high production rate) or in a pulsed mode that enables the control of the amount of energy delivered to the reaction. Together with other conventional spray process parameters, it allows producing either amorphous particles or single-crystalline ones (Sublemontier *et al.*, 2011).

A typical laser pyrolysis reactor consists in a vacuum-type chamber with two KCl or ZnSe windows (transparent at 10.6 µm) that allow the laser beam to cross the chamber. At the center of this chamber, the precursor aerosol is introduced through a nozzle perpendicularly to the laser beam. The reaction is confined in the center of the reactor by a flow of inert gas (argon) concentric to the precursor nozzle. The laser power is usually in the 100–2000 W range. The reaction temperatures depend on laser parameters, but also on the absorption properties of the reaction zone (concentration and absorption coefficient of the absorbing species). The resulting temperatures are typically in the 600–2000°C range.

In conclusion, thermal spray pyrolysis and laser spray pyrolysis appear as complementary methods, each of them being able to synthesize oxide or non-oxide complex nanomaterials in weighable amounts. When the very small sizes are not mandatory, when no absorbing precursor is available, or when this latter requires long residence time to be completely reacted (PDC routes for example), use of a furnace should be selected. When the final grain size should be smaller than 50 nm and more generally for silicon bases non oxide ceramics, laser pyrolysis is a process of choice.

Table 1 summarizes the characteristics of the laser and the furnace pyrolysis.

Powder Traps

The aerosol pyrolysis can lead to powders with primary particles size much smaller than 100 nm. They can nevertheless efficiently be trapped using a micro-porous filters (fiber fabrics, porous metallic or ceramic tubes...) because these primary particles are agglomerated and form larger objects.

Fig. 4 resumes the properties which can be changed by varying parameters during the ceramic synthesis by spray pyrolysis. The impact of these parameters will be treated in different examples in the last paragraph of this document.

Particles Growth Phenomena

Several mechanisms can be experienced by the droplets when they enter the heated zone of the reactor, leading to the formation of solid particles. Depending on these mechanisms, the morphology of the obtained products will be strongly affected. When properly controlled, aerosol processes actually offer the possibility to tune the shape and structure of the obtained products from

Fig. 4 Evolution of materials features (at the bottom part) with the parameters adjusted (at the top of the diagram) during pyrolysis.

Fig. 5 Main particles formation mechanisms encountered in spray pyrolysis.

chain-like type agglomerated nanoparticles to nanostructured micron-sized objects showing different morphologies (dense, porous, hollow).

The most generic and versatile approach concerns the use of a solution prepared from one or several metal salts or metalorganic dissolved in water or in an organic solvent. In this case, one considers the formation of one particle per droplet following mechanisms well described by [Messing *et al.* \(1993\)](#). As depicted in [Fig. 5](#), when entering the hot zone, the solvent vaporizes and the solute starts to condensate. Depending on solvent and salt properties or process parameters, this condensation can take place in volume or at the surface of the droplet. In the first case, the precipitate forms a relatively dense solid where the thermal reaction can take place and lead to the novel phase. A sintering phenomenon allows decreasing the porosity in this solid and leads to the final particle with a size within the micron range. In the second case, the vaporized solvent flows through the porous precipitate at the surface of the droplet, leading to a hollow solid particle at the end of the drying stage. Thermal reaction takes place in this shell, leading to hollow final particles. When the heating rate of the solvent is too high or the permeability of the shell is too low, an increase in pressure inside the drying droplet can break the shell and lead to irregular morphology of particles. In both cases the final particle size depends on the initial droplet size and the solution concentration.

Table 2 Spray pyrolysis parameters

<i>Solution conc. C (mol L⁻¹)</i>	<i>Atomizing frequency f (kHz)</i>	<i>Gas flow rate Q (L min⁻¹)</i>	<i>Furnace temperature T (°C)</i>
0.0025	850	3	400
0.025	2500	6	1000

When two different species are mixed in the solution, the precipitation step can be homogeneous (both precursors precipitate in volume or at the surface at the same time), or heterogeneous. In this latter case, core-shell structures can be obtained with a core constituted by the material that condensates first. More advanced structures (for example with controlled porosity) can be achieved using surfactants, as will be presented later in the examples section.

Nevertheless, the “one particle per droplet” or droplet-to-particle rule is no longer relevant when the precursor is completely vaporized. This happens when a liquid precursor is employed (for example titanium isopropoxide or tetrachloride for titanium based compounds), or when the process temperature and the heating rate are high enough to vaporize the precursor together with solvent before the pyrolysis reaction takes place in a condensed solute. Such conditions are frequently met in laser, plasma or flame spray processes, and lead to the formation of small nanoparticles agglomerated in poorly dense chain-like structures. In this case, the growth mechanisms are similar to the ones encountered in gas-phase processes and rely on nucleation and growth phenomena (Flagan and Lunden, 2007): condensation of the supersaturated gaseous phase upon fast cooling, growth by coagulation, aggregation and finally agglomeration during the temperature drop. Depending on the nucleation rate and on the residence time in the hottest reaction zone (coagulation phenomenon), the primary particles size in the agglomerates can be as small as few nanometers or reach several hundreds of nanometers. When very small nanoparticles are required, this reaction path should be favored versus droplet-to-particle mechanisms.

Combined or different mechanisms are reported in the literature for more specific aerosol processes using for example solid particles suspensions as precursors, combined liquid and gaseous precursors or sol-gel derivated processes (Debecker *et al.*, 2018). These more specific approaches will not be presented here.

The next section will present several examples taking advantage of these multiple growth phenomena to obtain advanced ceramic powders.

Examples

Control of Nanopowders Size and Composition

In this part, several examples are presented to illustrate the effect of experimental parameters of the spray pyrolysis processes (nature of precursors, pyrolysis temperature, nature of the pyrolysis atmosphere etc.) on the particle size and size distribution, and to demonstrate the ability of these processes to produce nanopowders with homogeneous complex compositions and controlled crystalline phases.

Nanopowders synthesis in the GdCeO system (Goulart and Djurado, 2013)

In this study, the authors are interested in synthesizing gadolinia-doped ceria nanostructured particles $\text{Ce}_{0.8}\text{Gd}_{0.2}\text{O}_{1.9}$ (CGO), with a control of the morphology of the as-formed powders. These materials are quite useful in the field of fuel cells (SOFC).

Spray pyrolysis of nitrate-based precursors was used to fabricate fine and polycrystalline $\text{Ce}_{0.8}\text{Gd}_{0.2}\text{O}_{1.9}$ (CGO) powders with controlled microstructure in a one-step process varying four spray-pyrolysis parameters: precursor solution concentration, atomizing frequency, carrier gas flow rate, and pyrolysis temperature, as shown in the Table 2.

The authors have shown that the particle morphology is mainly affected by the concentration of the precursor solution and the furnace temperature, and it is not dependent on the frequency of the ultrasonic atomizer and the carrier gas flow rate. All the powders obtained are generally composed of ovoid and/or spherical shaped and smooth particles, as shown in Fig. 6. In fact these submicron size particles have a hard-aggregated structure of primary particles with nanometer size that will be referred as crystallites.

The authors have performed an interesting statistical analysis to quantify the influences of the main process parameters and their interactions on the particle size, particle size distribution and crystallite size. Ovoid, dense and monodispersed particles with a peak diameter < 150 nm are obtained in one step at only 400°C by reducing the precursor solution concentration to 0.0025 mol L⁻¹ for a high atomizing frequency of 2500 kHz whatever is the flow rate. In these conditions, particles are found to be smaller with a narrower distribution. Porous and uneven particles are obtained when the pyrolysis temperature and concentration of precursor solution are increased whatever the flow rate and the frequency. The combination of both low pyrolysis temperature and low precursor solution concentration strongly affects the synthesis towards a smaller mean particle size, narrower particle size distribution and smaller mean size of the primary particles. Single phase cubic fluorite CGO was detected by XRD. The mean size of the primary particles decreased from 21.2 to 3.7 nm as the pyrolysis temperature changed from 1000 to 400°C while the precursor solution concentration was ten times smaller for the same atomizing frequency and flow rate.

Grain morphology control through the precursor solution in laser spray pyrolysis: Example of C/N/Fe nanoparticles

Growing interest for proton-exchange membrane fuel cells (PEMFC) motivates the development of new catalysts for the oxygen reduction reaction (ORR) without noble metals such as Pt. In this context, recent work was published dealing with C/N/Fe nanoparticles synthesis by laser spray pyrolysis (Perez *et al.*, 2018). Indeed, peculiar structures of carbon containing nitrogen in specific configuration show relevant activity towards ORR. Moreover, the presence of Fe during the synthesis of these C/N materials appears to favor the formation of the nitrogen sites with ORR activity.

In this paper, two different types of liquid solutions were used, both being sprayed to the reactor by ultrasonic device, with a strong effect on the final morphology of the obtained particles. The first type is a mixture of pyridine ($\text{C}_5\text{H}_5\text{N}$, acting as C and N source) with a suspension of goethite (FeOOH) nanoparticles in ethanol as Fe source. The second type is a solution of Fe acetylacetonate ($\text{Fe}(\text{C}_5\text{H}_7\text{O}_2)_3$) in pyridine. In both case precursors were sprayed using an ultrasonic device and the resulting aerosol was carried to the reaction chamber by a gaseous flow made of a mixture of argon and NH_3 . This carrier gas flow ratio $\text{NH}_3/(\text{Ar} + \text{NH}_3)$ was found to strongly influence the electronic structure of the products as probed by XPS, and consequently the ORR performance as well. Indeed, in such synthesis NH_3 has several roles: laser absorbent (thus effect on reaction temperature), N source, nitriding effect on Fe favoring nitride phases, and corrosive effect on C generating porosity. The nature of the solution appears to have its influence on the final performance too: an important effect on the powder morphology is observed (see Fig. 7). Goethite based suspension seems to favor droplet-to-particle mechanisms with the formation of large spherical objects, while the solution approach seems to lead to vapor phase growth phenomena with a main population of small nanoparticles forming fractal-like poorly dense agglomerates.

Towards complex crystalline structures: Nasicon nanopowders

Development of post-Lithium batteries such as Sodium-ion batteries requires research activity on electrodes materials able to withstand the rapid insertion of the “large” Na^+ ion. In this context, large interstitial space structures such as the ones encountered in layered transition sodium oxides materials are of great interest. Among these materials, sodium super ionic conductors (Nasicon) with generic formula $\text{Na}_x\text{M}_2(\text{PO}_4)_3$ ($M = \text{Ti}, \text{V}, \dots$) draw peculiar interest. In a 2015 article, promising electrochemical performances were recorded with $\text{Na}_3\text{V}_2(\text{PO}_4)_3/\text{C}$ nanocomposites prepared by thermal spray pyrolysis (Mao *et al.*, 2015).

To synthesize these particles, the authors used a solution of NH_4VO_3 , $\text{NH}_4\text{H}_2\text{PO}_4$, Na_2CO_3 in water and citric acid sprayed into the furnace at $50 \mu\text{L min}^{-1}$ with argon carrier gas at 3 L min^{-1} . The pyrolysis temperature was 600°C . Crystalline powders were obtained after 3 h annealing of the collected particles at 800°C under argon. These particles were compared to other ones prepared by a more conventional sol-gel process.

SEM pictures of the obtained particles show typical structures of droplet-to-particle conversion (see Fig. 8). The large spherical and hollow particles ($2\text{--}10 \mu\text{m}$) are constituted by smaller sintered grains (tens to hundreds nanometers) forming a porous wall

Fig. 7 SEM pictures of C/N/Fe particles obtained for different values of the carrier gas ratio R from goethite suspension in ethanol/pyridine (a), and (b) from Fe acetylacetonate solution in pyridine. Reproduced from Mao, J., Luo, C., Gao, T., Fan, X., Wang, C., 2015. Scalable synthesis of $\text{Na}_3\text{V}_2(\text{PO}_4)_3/\text{C}$ porous hollow spheres as a cathode for Na-ion batteries. *Journal of Materials Chemistry A* 3, 10378–10385.

together with a carbon layer. This structure contrasts with the one obtained by the sol-gel process showing aggregated irregular shapes of 1–8 μm objects.

Both types of particles show the same crystalline $\text{Na}_3\text{V}_2(\text{PO}_4)_3$ phase (see XRD in [Fig. 9](#)), but differ in their specific surface: $55.5 \text{ m}^2 \text{ g}^{-1}$ for sprayed particles versus $21.0 \text{ m}^2 \text{ g}^{-1}$ for sol-gel derivative ones. The difference on obtained porosity is clearly seen on adsorption curves (see [Fig. 9](#)), and appears as the direct consequence of the hierarchical porous structure observed in the sprayed particles.

Nanopowders synthesis in the SiCN system (Chehaidi *et al.*, 2011a)

Processing of dense silicon nitride-based materials needs sintering aids introduction such Al_2O_3 , Y_2O_3 , MgO , etc. A new route to produce dense silicon nitride-based materials, from nanopowder synthesis followed by a sintering step, seems to be more promising. An original approach is to favor an atomic scale distribution of sintering aids ($\text{Al}_2\text{Y}_2\text{O}_3$) which should lead to an homogeneous microstructure after densification. This work deals with the elaboration of SiCN_{YO} ultrafine powders by spray pyrolysis from a hybrid precursor. An yttrium organometallic (silylated yttrium acetate) was synthesized and mixed in a liquid silazane (hexamethyldisilazane) and the SiCN_{YO} powder synthesis was undertaken by spray-pyrolysis process. The pyrolysis conditions are: carrier total gas flow rate = 3 L min^{-1} and furnace temperature = 1400°C . In order to explore the influence of the nature of the reactive atmosphere on the powders characteristics two kinds of atmosphere with variable gas content were considered: Ar/NH_3 (75/25)% and $\text{Ar}/\text{H}_2/\text{NH}_3$ (65/10/25) %.

The morphology and the grain size distribution of the resulting particles were observed by the FEG-SEM image ([Fig. 10](#)). Spherical and solid particles with a grain size comprised between 30 and 100 nm have been obtained.

As shown [Fig. 10](#), a bimodal particles size distribution is observed whatever pyrolysis atmosphere is used. As shown in [Fig. 10\(a\)](#), the diameter of the largest grains is between 70 and 100 nm and the smallest ones is centered on 50 nm. During aerosol generation, two different mechanisms could be at the origin of this phenomenon as explained by [Chen *et al.* \(2008\)](#): one-particle-per-drop

Fig. 9 XRD diagrams recorded on aerosol (sprayed) particles and sol-gel derivate ones showing $\text{Na}_3\text{V}_2(\text{PO}_4)_3$ structure (left); and (right) adsorption curves recorded for these materials. Scalable synthesis of $\text{Na}_3\text{V}_2(\text{PO}_4)_3/\text{C}$ porous hollow spheres as a cathode for Na-ion batteries. *Journal of Materials Chemistry A* 3, 10378–10385.

Fig. 10 FEG-SEM micrographs of powders synthesized at 1400°C with 3 L min^{-1} flow rate of (a) $\text{Ar}/\text{H}_2/\text{NH}_3$ (65%–10%–25%) and (b) Ar/NH_3 (75%–25%).

mechanism for the larger particles and gas-to-particle conversion mechanism for the smaller ones. In addition to these two proposed mechanisms, the carrier gas composition seems to have a significant effect on the particle size distribution. Whatever the spraying atmosphere, two particle distributions are observed. In one hand, under Ar/H_2 spraying, (Fig. 10(a)), the average diameters are around 80 nm and 50 nm for the larger and the smaller particles, respectively. In the other hand, under Ar spraying, (Fig. 10(b)), the size of the larger particles is still the same whereas, for smaller particles, the diameter is reduced to 30 nm. Under a reactive carrier gas (Ar/H_2) the reactivity between particles and gas phase should promote the growing of the individual particles. In return, under an inert carrier gas (Ar), the particles-gas exchange seems to be limited and prevent the smaller particles from enlarging.

Complementary work was also achieved by the same group with aluminum based sintering additive following the same precursor engineering successful approach (Chehaidi *et al.*, 2011b).

A similar pathway was followed using laser spray pyrolysis with the same objective of preparing $\text{SiCN}/\text{Al}/\text{Y}/\text{O}$ nanopowders (Cauchetier *et al.*, 1999). HMDS was also used as $\text{Si}/\text{C}/\text{N}$ precursor because it shows an efficient absorption band of the laser wavelength, and was simply mixed with different Al and/or Y alkoxides with varying ratios. The obtained liquid was used as prepared or heated and/or diluted with isopropanol in order to decrease its viscosity, and was subsequently sprayed by an ultrasonic device towards the reactor, carried by an argon flow. Obtained powders were amorphous with sizes in the 20–30 nm range and specific surfaces ranging from 66 to $110 \text{ m}^2 \text{ g}^{-1}$. Production rate varies from 30 to 67 g h^{-1} depending on feeding parameters (precursor nature, solution heating or dilution, argon carrier gas flowrate). Interestingly, the ratio of the Al or Y

Fig. 11 (a) Schematic diagrams for the preparation of porous particles with ordered pores using organic template particles. (b and c) SEM images of self-assembled porous SiO_2 particles prepared from colloidal mixtures of silica nanoparticles and PSL. Reproduced from Chang, H., Okuyama, K., 2002. Optical properties of dense and porous spheroids consisting of primary silica nanoparticles. *Journal of Aerosol Science* 33, 1701–1720.

additives atoms over Si atoms in the starting solution (0.05–0.07) was generally found close to the same ratio measured in the obtained products. Additional work by the same group dealt with the study of the electronic structure of these materials by XPS, and concluded on the presence of a YSiAlON layer at the surface of the grains after annealing at 1600°C during 1 h under N_2 (Ténégal *et al.*, 2000), which was assumed to be favorable for liquid phase sintering process. While the introduction of sintering additives during the particle growth appeared successful, the poor thermal stability of the powders was pointed out with relative weight losses as high as 30% upon annealing at 1500°C under N_2 . Addition of silane to the reaction (SiH_4 acts both as laser absorber and Si source), together with the use of NH_3 (laser absorber and N source), allowed a better control of the powders composition and was found to enhance the thermal stability of the products but also lead to a more expensive process (Dez *et al.*, 2002).

Core-Shell Particles and Advanced Structures

Porous particles

The synthesis of porous powders can be undertaken by spray pyrolysis. Chang and Jang (2014) have produced an excellent and comprehensive review on the preparation and application of porous particles prepared using aerosol methods. The typical experimental setups as well as general experimental procedures for the preparation of porous particles have been presented and the various routes for the controlled synthesis of porous particles (including self-assembled porous particles made using organic templating, and pore size- and porosity-controlled particles from aggregated nanoparticles) have been discussed. The general experimental procedure for the preparation of porous particles is as follows: (1). Preparation of the colloidal precursor. (2). Spraying of the colloidal precursor into droplets. (3). Droplet-to-particle conversion by evaporation of the solvent and/or pyrolysis of the precursor in the furnace. (4). Removal of organic templates in the furnace. (5). Collection of porous particles. Fig. 11 shows a schematic diagram for the preparation of porous particles with ordered pores using organic template particles.

This approach is also illustrated in the work of Hyodo *et al.* which deals with the synthesis of porous In_2O_3 powders (Hyodo *et al.*, 2017).

For a cost-effective process, it is necessary to produce pore size controlled particles without organic templates. As mentioned before, the aggregated nanoparticles suspended in the starting colloid affect the pore size of the final porous particles. The preparation of porous particles can be managed from different colloidal suspensions composed of well-dispersed nanoparticles and aggregated nanoparticles. SEM images and pore size distributions of (1) the meso-porous and (2) the macro-porous SiO_2 particles prepared from the above different colloidal suspensions are shown in Fig. 12. Pore size-controlled particles were successfully prepared without any organic templates. The porosity of porous particles can be easily controlled by manipulating the size of the primary nanoparticles contained in the starting colloidal suspension.

Fig. 12 (a and b) SEM images and (c) pore size distributions of pore size-controlled SiO₂ particles prepared from different colloidal suspensions composed of (a) well-dispersed nanoparticles and (b) aggregated nanoparticles. Reproduced from Jang, H.D., Kil, D.S., Chang, H., *et al.*, 2011. Preparation of nanoporous SiO₂ particles and their application in drug release control. *Journal of Nanoscience and Nanotechnology* 11, 4169–4173.

Advanced morphology of particles obtained by spray pyrolysis: Core-shell and yolk-shell structures

Spray pyrolysis offers the possibility to control the final morphology of the particles thanks to the droplet-to-particle mechanisms where decomposition/reaction and growth phenomena take place inside a spherical micro-reactor (i.e., the droplet). This possibility provides a decisive advantage when it comes to produce core-shell (a core-particle at the center with its surface protected by a shell) or yolk-shell (a particle with a “free” surface placed inside a larger hollow shell) particles. Such structures draw particular interest for Li-ion battery applications where performances and durability of the electrodes materials are governed by their tolerance to volume changes upon Li insertion and surface reactions with electrolyte.

Core-shell structures can be obtained with single-step spray pyrolysis process from solutions containing the different precursors for both core and shell. In many case the process takes advantage of the difference in physical properties between the selected precursors to ensure the initial precipitation of the core within the droplet while the shell precursor is expelled towards its surface. Carbon shells are among the most common coatings that can be encountered in the literature; a relevant example is the one step synthesis of tin oxide cores coated by carbon for energy storage applications (Hong and Kang, 2015). In this work, authors used an aqueous solution of Sn oxalate (C₂O₄Sn) and polyvinylpyrrolidone that was subsequently sprayed by an ultrasonic device into a furnace heated at 650°C. The obtained objects show a mean diameter of 770 nm with a C shell of about 30 nm in thickness (see Fig. 13(a)). Following the same approach, magnetic iron-based cores coated by C were synthesized by single-step laser spray pyrolysis for medical imaging applications (Leconte *et al.*, 2007). Other type of shell was also addressed by the same group using laser spray pyrolysis, still for the same magnetic contrast agent application, replacing carbon by silica as coating layer (Bomati-Miguel *et al.*, 2005). Nevertheless, when the shell material precursor does not “naturally” migrate towards the droplet surface upon heating versus the core precursor, alternate strategy can be followed. As an example, a sequential thermal spray pyrolysis reactor was developed to synthesize TiO₂-RuO₂ core-shell particles (Stopic *et al.*, 2013). The core precursor (Tetra-n-butyl orthotitanate (C₁₆H₃₆O₄Ti)) is sprayed in a first furnace, enabling the growth of the TiO₂ particles which are subsequently conveyed as a dry aerosol to a second furnace where they meet a second aerosol stream coming from another ultrasonic device spraying the shell precursor (ruthenium chloride (RuCl₃)). This latter precursor reacts around the solid TiO₂ particles and forms a continuous RuO₂

shell. In this case, syntheses of core and shell materials are independent, and thus almost any core-shell couple can be achieved. Similar strategy was followed using gas phase laser pyrolysis with a two stage reactor for the synthesis of Si cores coated by C (Sourice *et al.*, 2013), that could also be used with liquid precursors. At the first stage, the Si precursor (SiH_4) crosses the laser beam to form the Si cores which are carried as a dry aerosol to a second nozzle where they are mixed with a C precursor (C_2H_4). This latter nozzle introduces the mixture to the second stage, crossed by the laser beam using a set of mirrors, leading to the growth of the C shell around the Si cores by heterogeneous nucleation (gas phase process). Such two-steps approaches, using furnace or laser, appear very versatile but still show limitations. The precursor's decomposition products coming from the core growth at the first step are introduced in the second step together with the solid particles, which can lead to contamination of the materials. Moreover, when an oxide core has to be coupled to a non-oxide shell, oxygen coming from first step constitutes an issue for the second step.

Yolk-shell structures are the matter of huge interest from the scientific community, especially for energy storage applications. When compared to core-shell structures, their elaboration process is generally more complex. Organic buffer layer (citrate for example) is sometimes used to fill the space between the inner particle and the shell, and has to be removed afterwards (heat treatment, washing, etching...). A suspension of nanoparticles previously synthesized can also be used, mixed with the shell precursor and subsequently sprayed to the reaction zone (see for example the elaboration of $\text{MnFe}_2\text{O}_4 - \text{SnO}_2$ yolk-shell particles) (Li *et al.*, 2017). Nevertheless, some yolk-shell structures were obtained using single step spray pyrolysis. Relevant example is shown in Fig. 13(b) for the synthesis of $\text{LiNi}_{0.5}\text{Mn}_{1.5}\text{O}_4$ yolk-shell powders (Choi *et al.*, 2013). The authors used an aqueous solution of lithium nitrate (LiNO_3), nickel nitrate ($\text{Ni}(\text{NO}_3)_2$), and manganese nitrate ($\text{Mn}(\text{NO}_3)_2$). This solution was mixed with sucrose which acts as a carbon source useful for the formation of the specific structure. Indeed, according to the authors, the final structure results from a succession of contraction and combustion steps after the first formation of a metal oxide and carbon composite upon droplet heating, the center of the composite particle being incompletely burnt because of insufficient oxygen diffusion.

As it has been seen in the case of yolk-shell structures, suspensions of pre-synthesized objects can be mixed with other precursors and jointly be sprayed to the pyrolysis set up. Using such an approach, composite powders can easily be obtained with efficient contact between the different components of the composite as their association takes place at high temperature. A very popular application is the elaboration of composites with carbon structures such as nanotubes or graphene that are known for their mechanical and transport properties. These numerous approaches will not be addressed here but interesting review papers can be found in the literature (Zhao *et al.*, 2016; Jung *et al.*, 2014).

Calcination and Phase Transformations

Gary L. Messing, Pennsylvania State University, University Park, PA, United States

Industrial scale powder synthesis involves mixing tonnage-scale lots of metal carbonate, hydroxide and oxalate precursor powders, and/or metal oxide powders to produce complex, or mixed metal, oxide powders by calcination (e.g., $\text{MgCO}_3 + \gamma\text{-Al}(\text{OH})_3 \rightarrow \text{MgAl}_2\text{O}_4$). In this case calcination involves a lower temperature step to first decompose the MgCO_3 to form MgO and $\gamma\text{-Al}(\text{OH})_3$ decomposition to form $\gamma\text{-Al}_2\text{O}_3$, at higher temperature $\gamma\text{-Al}_2\text{O}_3$ is transformed to $\alpha\text{-Al}_2\text{O}_3$, and at even higher temperature the calcination process involves the solid-state reaction between MgO and $\alpha\text{-Al}_2\text{O}_3$ particles to form MgAl_2O_4 spinel. Small batch synthesis may involve mixing highly water-soluble metal salts like acetates, chlorides and nitrates to achieve homogeneous solutions of the metal cations. These solutions are rapidly co-precipitated to preserve the atomic-scale homogeneity of the metal ions by forming a mixture of the respective sparingly soluble carbonate, hydroxides or oxalates. In contrast to the micrometer-scale powders used in large-scale industrial processes, co-precipitated particles are submicrometer in size as a result of the rapid co-precipitation step. The scale and uniformity of mixing of the co-precipitated powder is finer and more uniform than possible by dry mixing coarser powders.

A metal salt solution can also be rapidly dried to precipitate a homogeneous mixture of the metal salts. For example, PLZT $[(\text{Pb}_{0.85}\text{La}_{0.15})(\text{Zr}_{0.8}\text{Ti}_{0.2})\text{O}_3]$ can be synthesized by dissolving $\text{Pb}(\text{NO}_3)_2$, $\text{La}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, $\text{ZrO}(\text{NO}_3)_2 \cdot n\text{H}_2\text{O}$ and $\text{Ti}(\text{i-OC}_3\text{H}_7)_4$ in water to achieve atomic scale mixing of the cations. Drying the solution results in the co-precipitation of the metal salts. In this case calcination involves a low temperature (e.g., $< 200^\circ\text{C}$) step to remove the structural water of hydration, decomposition of the anhydrous metal nitrates at $550\text{--}600^\circ\text{C}$, and formation of PLZT powder by the solid state reaction between PbO , La_2O_3 , ZrO_2 and TiO_2 by heating to $950\text{--}1000^\circ\text{C}$.

The objective of calcination is to produce a thermodynamically stable form of a powder so that the above decomposition processes and shrinkage from phase formation do not occur during sintering the ceramic part, and the particles formed are not aggregated by partial sintering prior to dispersion and forming. Table 1 lists examples of calcination processes and ceramic powders that are commonly produced by calcination. Calcination is used mainly for thermal decomposition reactions, phase transformation and solid-state reactions. Another objective may be to remove impurities remaining from a vapor synthesis process like removal of adsorbed HCl in Si_3N_4 powder derived from nitridation of SiCl_4 gas.

Decomposition Reactions

Thermodynamics has a major impact on decomposition reactions because the rate of decomposition is directly related to the reaction temperature and product gas concentration required for reaction. The free energy of the decomposition reaction is given by

$$\Delta G^0 = \Delta H^0 - T\Delta S^0 \quad (1)$$

where G^0 is the Gibbs free energy for the reaction, ΔH^0 is the enthalpy of the reaction and $T\Delta S^0$ is the entropy of the system; all at standard state. The equilibrium temperature for the reaction can be determined by calculating the free energy of formation from standard reference tables. Plots of ΔG^0 versus temperature, as shown in Fig. 1 (referred to as an Ellingham, or standard free energy

Table 1 Examples of calcination processes for producing ceramic powders

Decomposition

Phase Transformation

Solid State Reaction

Carbothermal process (Acheson process)

Fig. 1 Standard free energy of reaction as a function of temperature and equilibrium gas pressure for decomposition of metal carbonates and magnesium hydroxide. Reproduced from Ring, T.A., 1996. Fundamentals of Ceramic Processing and Synthesis. Boston, MA: Academic Press.

of formation, plot) provide practical insights about how product gas pressure and temperature affect the relative thermal stability of materials (Gaskell, 1995). To illustrate the importance of thermodynamics, consider the decomposition of $\text{CaCO}_3(\text{s})$ to form $\text{CaO}(\text{s})$ and $\text{CO}_2(\text{v})$. For solids at standard conditions, the activity is assumed to be one. Thus, the equilibrium constant $K_{\text{eq}} = (\text{CO}_2)$ and for a gas, $(\text{CO}_2) = P_{\text{CO}_2}$. Thus,

$$\Delta G_{\text{rx}} = \Delta G_{\text{rx}}^0 + RT \ln (K_{\text{eq}}) \quad (2)$$

At equilibrium, the free energy of the reaction ΔG_{rx} is zero and

$$\Delta G_{\text{rx}}^0 = -RT \ln (P_{\text{CO}_2\text{eq}})$$

In general, we can write

$$\Delta G_{\text{rx}}^0 = -RT \ln \left(\frac{P_{\text{CO}_2}}{P_{\text{CO}_2\text{eq}}} \right)$$

If ΔG_{rx}^0 is positive, then decomposition does not occur at that temperature and product gas pressure and when ΔG_{rx}^0 is negative decomposition takes place.

Note that for metal hydroxides, like $\text{Mg}(\text{OH})_2$, the free energy equation takes the form

$$\Delta G_{\text{rx}}^0 = -RT \ln \left(\frac{P_{\text{H}_2\text{O}}}{P_{\text{H}_2\text{Oeq}}} \right) \quad (3)$$

Because the product gases of carbonates and hydroxides exist in the atmosphere at low concentrations, atmospheric conditions play more of a role during decomposition of these types of precursors as well as metal oxalates $[\text{C}_2\text{O}_4^{-2}]$, acetates $[\text{CH}_3\text{COO}^-]$, and citrates $[\text{C}_6\text{H}_5\text{O}_7^-]$, which decompose into gaseous H_2O , CO , and CO_2 . From Fig. 1 the equilibrium temperature for one atmosphere of product gas occurs at $\Delta G_{\text{rx}} = 0$. At the equilibrium condition, $T_{\text{eq}} = 1156\text{K}$ (883°C) for CaCO_3 , 672K (399°C) for MgCO_3 and 550K (277°C) for $\text{Mg}(\text{OH})_2$. $P_{\text{CO}_2} = 5 \times 10^{-3}$ atm and $P_{\text{H}_2\text{O}} = 0.05$ atm in air, and thus, when calcined in air T_{eq}

Fig. 2 Rate of decomposition of CaCO_3 in CO_2 atmosphere. Reproduced from Hyatt, E.P., Cutler, I.B., Wadsworth, M.E., 1958. Calcium carbonate decomposition in carbon dioxide atmosphere. *J. Am. Ceram. Soc.* 41, 70–74.

decreases to 810K for CaCO_3 , to 480K for MgCO_3 , and to 445–465K for $\text{Mg}(\text{OH})_2$. For practical reasons, decomposition reactions are carried out at a higher temperature than the minimum temperature/pressure conditions predicted by thermodynamics. [Mu and Perlmutter \(1981\)](#) is a useful reference for decomposition reactions and decomposition temperatures of commonly used metal carbonates, metal acetates, metal oxalates and metal hydroxides.

The kinetics of decomposition reactions are governed by a variety of factors that fundamentally determine whether the reaction is controlled by (1) nucleation (interface reaction), (2) mass transfer of the product gas, or (3) heat transfer. During decomposition nucleation is less important because the powder mass is nearly all interfaces and nucleation readily occurs at elevated temperature. As noted above, the reaction gas pressure plays a critical role during decomposition reactions. [Fig. 2](#) illustrates the effect of product gas pressure on the decomposition of CaCO_3 . Recall from [Fig. 1](#) that T_{eq} in air is 810K (537°C) but T_{eq} increases to 1123K (850°C) at a CO_2 pressure of 0.4 atm. The temperature at which decomposition begins decreases as the product gas pressure in the system decreases. For a single particle, the gas pressure controlling the rate of decomposition is the pressure adjacent to the decomposition front inside the particle since that is the site of highest product gas concentration and thus controls the equilibrium temperature of decomposition.

The rate of powder decomposition in a saggar (i.e. a ceramic vessel used for calcination) can be controlled by the rate of gas diffusion through the reacted powder and thus depends significantly on powder bed depth in the saggar, and powder size, pore size and packing density. So that reactions are not rate-limited by gas diffusion through the powder bed, the powder is often fluidized, or the bed is continuously stirred in a rotary calciner. Likewise, any method to remove the product gas accelerates the process, such as with a vacuum or the use of a sweep gas. Using the above approaches ensures heat transfer controls the kinetics of decomposition.

The shrinking core model in [Fig. 3](#) has been used to model decomposition reactions. The model is characterized by a solid unreacted core, and a sharp interface between the unreacted core and decomposed metal oxide layer. The model accounts for gas flow from the particle surface to the furnace ([Eq. 6](#)) and from the reaction interface through the porous metal oxide shell ([Eq. 5](#)). The product of the decomposition reaction is nanocrystalline and thus the unreacted core is surrounded by a shell of <100 nm nanopores. The nanoporosity of the reaction product decreases the rate of mass transport of the product gas relative to in the furnace and thus mass transport through the nanoporous shell surrounding the solid unreacted core can be rate-limiting because the internal gas pressure is higher than the ambient gas pressure. The nanoporosity of the new oxide decreases the thermal conductivity relative to the unreacted solid particles. [Eq. \(8\)](#) shows the heat transfer from the furnace to the particle surface and thermal conductivity ([Eq. 9](#)) through the porous metal oxide product layer ([Kingery et al., 1975](#)).

$$J_{\text{reaction interface}} = kr4\pi r^2(P_e - P_r), \text{ where } P_e = e^{-\Delta G^0/RT_f} \quad (4)$$

$$J_{\text{porous layer}} = 4\pi \frac{D'_{\text{CO}_2}(P_r - P_s)r_s}{r_s - r} \quad (5)$$

Fig. 3 Schematic of the partial decomposition of a spherical particle (e.g., CaCO_3) showing the solid unreacted core surrounded by a shell of porous, nanocrystalline metal oxide (e.g., CaO). The reaction is endothermic, requiring heat transfer to the reaction interface. The driving forces for heat transfer and mass transport for steady-state decomposition are expressed as temperatures and pressures in the furnace (T_f , P_f), at the particle surface (T_s , P_s), and at the reaction interface (T_r , P_r).

$$J_{\text{furnace}} = 4\pi r_s^2 \frac{D_{\text{CO}_2}}{\delta} (P_s - P_f) \quad (6)$$

where δ is the boundary layer thickness at the interface between the furnace and outside surface of the particle and D'_{CO_2} is the CO_2 diffusion rate through the porous metal oxide layer.

Heat transfer to the reacting particle is given by

$$q_{\text{reaction interface}} = \frac{4\pi r^2 \rho}{M} \Delta H_{T_f}^o \frac{dr}{dt} \quad (7)$$

$$q_{\text{furnace}} = h_s 4\pi r_s^2 (T_f - T_s) \quad (8)$$

$$q_{\text{porous layer}} = \frac{4\pi k (T_s - T_r) r r_s}{r_s - r} \quad (9)$$

where ρ is density of CaCO_3 , M is molecular weight, h_s is the heat transfer coefficient at the solid CaCO_3 surface, and k is the thermal conductivity of the porous CaO shell.

Fig. 4 illustrates how the center temperature of a large CaCO_3 crystal changes relative to the surface temperature when heated at 1332°C . The center of the crystal is about 450°C less than the surface temperature during most of the calcination process because the heat is absorbed at the reaction interface to sustain the endothermic decomposition reaction (Eq. 4). Only after 2 h does the center temperature start to increase. To increase the rate of reaction for a single particle, it is important to decrease particle size to reduce the distance between the heat source and particle core.

In powder beds the reaction front recedes from the powder bed surface into the reacting powder bed with time. The temperature at the reaction front is governed by the amount of heat required to sustain the typically endothermic reaction. The above example underscores the importance of heat transfer for bulk powder calcination because the powder bed depth in a saggar is orders of magnitude greater than the particle size. Shallow saggar fill depths, rotary calciners or fluidized beds are used to decrease the effects of powder bed depth on gas transport and heat transfer and to limit the effects of non-uniform heating and reaction during calcination. The mathematics underlying the rates of heat and mass transfer on decomposition reactions has been extensively reported for a wide variety of process conditions and calcination reaction types, including decomposition (Levenspiel, 1972; Turkdogan, 1980; Ring, 1996).

The overall reaction rate is controlled by the relative rates of heat transfer and mass transport. These processes are in series and thus the rate of the reaction is controlled by the slower rate process. In general, surface reaction control occurs at low temperatures since this is when the new phase is nucleated. The reaction is heat transfer controlled at intermediate reaction temperatures whereas mass transport of the product gas is rate-controlling at the highest temperatures. One means to accelerate the reaction is to increase the temperature. However, increasing temperature to $> \sim 50\%$ of T_m (K) (i.e., the Tammann temperature) of the product metal oxides increases the rate of solid state diffusion and causes coarsening (i.e., size enlargement of the nanoscale product phase), and sintering of the fine crystallite particles leading to formation of a hard, porous product phase referred to as an aggregate. Such multiparticle aggregates must be milled to break them into separate particles because multiparticle aggregates adversely affect subsequent densification of the shaped ceramic.

Solid-State Reactions

Most multicomponent ceramic materials (i.e., mixed metal oxides) are synthesized via a solid-state process. The uniformity of mixing and the length scale between the particle reactants have major influences on the time and temperature required to complete the reaction. Thus, to decrease diffusion distances most mixed metal oxides are synthesized by a solution approach in which the cations

Fig. 4 Variation of surface and center temperatures of an 8.3 cm diameter CaCO_3 sphere heated at 1332°C in 1 atm argon. Reproduced from Turkdogan, E.T., 1980. *Physical Chemistry of High Temperature Technology*. Boston, MA: Academic Press.

are intimately mixed in a liquid and co-precipitated or co-hydrolyzed to form a homogeneous mixture of the individual, sparingly soluble metal hydroxides, oxalates, or carbonates. It is important to note that the uniformity of the co-precipitated powder has a major influence on the path and kinetics of phase formation during subsequent heating (Narendar and Messing, 1997).

The degree of phase transformation versus time follows the typical S-shaped kinetics plot. The plot is characterized by an incubation period, a period of rapid reaction kinetics, and a period of decelerating kinetics. The incubation period is interpreted as the time required for the growth of nuclei of critical size. Once this size is achieved, the energetically favored growth or transformation of a new phase begins. The nucleation period can be reduced by increasing temperature, adding a flux, or by adding seed particles (see below).

Analysis of Transformation Kinetics

There are two approaches for analyzing phase transformation kinetics: (1) measurement of phase formation as a function of time at isothermal temperatures and (2) measuring the effect of heating rate on exothermic temperature. The first approach, called an Arrhenius analysis, uses quantitative x-ray analysis of the degree of phase development as a function of time for three or more isothermal temperatures. The data is then analyzed to extract the rate constants and activation energies at various degrees of reaction to determine rate-controlling processes. In this case many samples are needed to obtain an accurate activation energy for the transformation. Kissinger (1956) developed an alternative method using either differential scanning calorimetry or differential thermal analysis to obtain the activation energy for a phase transformation. The Kissinger analysis only requires the peak temperature of the exothermic phase transformation at various heating rates. The Kissinger equation is:

$$\ln \left[\frac{dT/dt}{T_m^2} \right] = - \frac{E_a}{R} \left(\frac{1}{T_m} \right) + B \quad (10)$$

$$B = \ln \left(\frac{AR}{E_a} \right) = \text{constant}$$

Fig. 5 YAG content at 1450°C as a function of critical diffusion distance. Schematics illustrate the influence of size and size ratio on completion of YAG phase formation. Reproduced from Kupp, E., Kochawattana, S., Lee, S., Mixture, S., Messing, G.L., 2014. Particle size effects on yttrium aluminum garnet (YAG) phase formation by solid-state reaction. *J. Mater. Res.* 29, 2303–2311.

where T is temperature in K , t is time, T_m is the peak temperature of the phase transformation, E_a is activation energy, A is the Arrhenius constant, and R is the gas constant. By plotting $\ln \left[\frac{dT/dt}{T_m^2} \right]$ versus $(1/T_m)$ for various heating rates one can obtain the activation energy from the slope, $-E_a/R$. The Kissinger approach has its limitations but is useful for limited study of irreversible single step reactions but fails for many reasons in complex systems (Vyazovkin, 2020).

There have been many attempts to model the kinetics of phase formation. In all approaches a linear fit of the degree of reaction to time and/or temperature is interpreted as representative of a single reaction mechanism. However, the analysis of the kinetics of reactions is complicated by non-spherical particle shapes, a distribution of number of contacts from particle to particle, mixing heterogeneity, and differences in particle sizes. Activation energies and rate constants obtained by curve fitting are useful for comparisons as a function of various parameters within the same study but often lack any fundamental meaning. To appreciate the complexity of these analyses see Ring (1996) and Khawam and Flanagan (2006).

Analysis of phase formation kinetics is particularly complicated by differences in particle size between reactant powders. Kupp *et al.* (2014) showed that the size ratio between Al_2O_3 and Y_2O_3 particles during formation of $\text{Y}_3\text{Al}_5\text{O}_{12}$ dramatically affects the reaction pathway and kinetics. It is known that Al^{3+} diffusion into Y_2O_3 particles is the rate-controlling process for YAG formation. Thus, the Y_2O_3 particle size establishes the critical diffusion distance affecting the degree of YAG formation. Fig. 5 shows that the reaction was near complete only when the Y_2O_3 particle size was less than 110 nm diameter and the number of Al_2O_3 particles in contact with Y_2O_3 was approximately 10 and the Al_2O_3 and Y_2O_3 particles have a size ratio near 1. This example illustrates that it is important to tailor the powder system for solid-state calcination by matching the particle sizes and size ratio of the reactant particles.

Seeding of Ceramic Reactions

Phase formation during calcination plays a major role in microstructure and property development in ceramic systems. Common to most ceramic reactions, variations in nucleation and growth determine the process temperature and time, product particle size, and chemical phase development. Seeding to direct ceramic transformations has been demonstrated in a variety of systems (Messing *et al.*, 1986). Homoepitaxy, in which the seed and desired phase have identical lattice parameters and crystal structures, is the most likely prospect for nucleation manipulation by seeding in ceramic systems. Besides selection by seed crystal structure and lattice parameter, it is important to determine the intrinsic nucleation frequency of the system being seeded. The intrinsic nucleation frequencies in transition alumina (e.g., γ - Al_2O_3 or θ - Al_2O_3) phase transformations to α - Al_2O_3 ranges from 10^9 to 10^{12} nuclei cm^{-1} . To nucleate a reaction and achieve smaller particle size after transformation, it is necessary to exceed the intrinsic nucleation frequency. Seed particle surfaces typically act as sites for multiple nucleation, making exact estimations of extrinsic nucleation frequency from seeding imprecise. However, we can calculate transformed particle size if the seed size and number frequency per volume are known.

An example of a seeded transformation is the introduction of α - Al_2O_3 particles to an γ - AlOOH gel (boehmite) that transforms to γ - Al_2O_3 at 500°C, to θ - Al_2O_3 at 900°C and to α - Al_2O_3 at 1200°C. Fig. 6 shows the unseeded phase transformation has an incubation period of ~ 16 min and takes over 6 h to completely transform to α - Al_2O_3 when heated at 1050°C. However, when 2.7×10^{13} α - Al_2O_3 seed particles cm^{-3} are introduced to the initial boehmite gel, the initiation of the θ to α - Al_2O_3 phase transformation is almost instantaneous, and the total time for complete transformation is decreased to ~ 16 min. The graph shows that increasing the seeding (nucleation) frequency increases the transformation rate in proportion to the number of transformation

Fig. 6 Alpha alumina phase formation (a) kinetics at 1050°C and (b) theoretical (Eq. 11) and experimental α -Al₂O₃ particle size as a function of α -Al₂O₃ seed number concentration (inset seeded alumina particles).

growth centers (i.e., seed particles). In this manner the nucleation-limited, solid-state transformation of θ -Al₂O₃ to α -Al₂O₃ was lowered by as much as 200°C relative to the unseeded α -Al₂O₃ phase transformation (Kumagai and Messing, 1985). The temperature for the intrinsic solid-state diffusional processes of the system limits further calcination temperature reduction. However, increasing the rate of transport by using “mineralizers” that react to form a liquid (V₂O₅) or vapor (HF, H₂O) with alumina has been shown to lower the alpha alumina transformation temperature by an additional 200–300°C. (Shelleman and Messing, 1988; Shaklee and Messing, 1994; Bagwell and Messing, 1999).

Assuming a single particle develops from each seed and the seeds are uniformly distributed in the transforming matrix, the particle size (PS) of the transformed material after seeding at a frequency f_s is

$$PS = kf_s^{-1/3} \quad (11)$$

where k is a correction factor for particle shape and the molar volume difference between the untransformed and transformed materials. Assuming no volume contribution from the seed particle, the predicted α -Al₂O₃ particle size obtained by seeding γ -AlOOH with 2.4×10^{14} α -Al₂O₃ seed particles cm⁻³ is 0.16 μm (Fig. 6(b) and (c)). This example illustrates that significantly smaller particles can be obtained by seeding a phase transformation.

Epitaxy

The principles governing seed characteristics are related to the ability of the seed crystal to favor oriented overgrowth (i.e., epitaxy) in the reacting system because of crystallographic matching. Solid-phase epitaxy, or the introduction of solid seed particles to a system undergoing a solid-state reaction as a means of controlling ceramic reactions, has been demonstrated to be an effective means to control solid-state kinetics, microstructure development and phase development (Messing *et al.*, 1986).

Epitaxy concerns the degree of lattice parameter matching (δ) during growth at the interface between a reacting system or matrix (a_α) and the seed crystal or substrate (a_β)

$$\delta = \frac{a_\alpha - a_\beta}{a_\beta} \quad (12)$$

The nucleation effectiveness of a seed crystal is related to the seed-matrix interfacial energy ($\gamma_{\alpha\beta}$) and the seed-matrix contact angle (θ).

$$\cos \theta = \frac{\gamma_\alpha - \gamma_\beta}{\gamma_{\alpha\beta}} \quad (13)$$

For low values of δ the seed and host matrix are coherently oriented at the interface and $\gamma_{\alpha\beta}$ ranges from 1 to 200 mJ m⁻². For larger degrees of lattice mismatch, the strained, incoherent interface is accommodated by dislocations and $\gamma_{\alpha\beta}$ is 200–500 mJ m⁻² (Porter and Easterling, 1992). For values of δ greater than $\pm 15\%$, the incoherent interphase interface energy is 1000 mJ m⁻² and there is no effect of the seed particle on nucleation (i.e., epitaxy does not occur). Seed crystals with a lattice parameter mismatch with the transformed product of less than $\pm 15\%$ are typically effective nucleation “catalysts”.

The addition of seed crystals lowers the free energy for nucleation (ΔG_{heter}) to less than that required for homogeneous nucleation (ΔG_{hom}) through its effect on the interphase interfacial energy and the seed-matrix contact angle:

$$\Delta G_{\text{heter}} = \Delta G_{\text{hom}} \{ (2 + \cos \theta)(1 - \cos \theta)^2 \} / 4 \quad (14)$$

For example, when $\theta = 10^\circ$, $\Delta G_{\text{heter}} \sim 10^{-4} \Delta G_{\text{hom}}$, demonstrating the significant reduction in nucleation energy afforded by seeding (Porter and Easterling, 1992).

Applying the principles of epitaxy, McArdle and Messing (1993) showed that $\alpha\text{-Fe}_2\text{O}_3$ with a 5.5% lattice parameter mismatch with $\alpha\text{-Al}_2\text{O}_3$, is an equally effective substrate for seeding the $\alpha\text{-Al}_2\text{O}_3$ transformation as $\alpha\text{-Al}_2\text{O}_3$ particles. An added benefit of $\alpha\text{-Fe}_2\text{O}_3$ seeds is <100 nm size particles can be chemically synthesized and thus it is easier to achieve 10^{14} seeds cm^{-3} number concentrations. It should be noted that as heteroepitactic seed particles like $\alpha\text{-Fe}_2\text{O}_3$ become smaller (e.g., $\alpha\text{-Fe}_2\text{O}_3$ seeding of $\alpha\text{-Al}_2\text{O}_3$), their reactivity and propensity for solid solution with the matrix increases. If there is a solid solution before the particle seeds the phase transformation then the seed particles may not be present to act as an effective seed.

Seeding Strategy

It has been shown that the seed number density, not the seed weight addition, is the more useful variable for understanding how seeding affects the transformation kinetics and particle size control during the θ to $\alpha\text{-Al}_2\text{O}_3$ phase transformation (Kumagai and Messing, 1985). The seed number density, f_s , depends on the seed size, d , according to

$$f_s = \frac{N_s}{V_{\text{tot}}} = \frac{6m_x}{\pi\rho_o V_{\text{tot}}} \sum_{i=1}^n \frac{wf_i}{d_i^3} \quad (15)$$

where N_s is the number of seeds, V_{tot} is the total volume of the powder, m_x is the weight of the seeds added, ρ_o is the theoretical density of the seed material, and d_i is the seed size for a given weight fraction, wf_i .

Seeding by addition of solid seed particles is limited by the availability of sufficiently small particles ($< 0.1 \mu\text{m}$) to achieve high nucleation number frequencies (i.e., N_s of $> 10^{14} \text{ cm}^{-3}$). Therefore, an important prospect is the development of in-situ chemical processes for nucleation control. Huling and Messing (1990) mixed molecular and colloidal gels to form a hybrid gel for the in-situ nucleation and transformation of mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$). Upon heating, the molecular gel transformed to mullite crystallites in the colloidal gel matrix, providing nuclei for the bulk transformation of the colloidal gel to mullite. This example illustrates the potential for the control of solid-state transformations by controlling the original chemistry of the system to produce in-situ growth of seed crystals as a means of controlling nucleation of the bulk material.

Phase Separation

Despite homogeneous cation distribution in a precipitate or gel, phase separation is commonly observed during oxide formation in a variety of heterometallic systems. The difference in the crystallization behavior of seemingly homogeneous systems and the influence of processing and impurities on crystallization can be understood from nucleation theory. The classical steady-state homogeneous nucleation rate is given by J_s^* .

$$J_s^* = z\beta N \left(\exp \frac{\Delta G_{\text{hom}}^*}{kT} \right) \quad (16)$$

where z is the Zeldovich factor, β is the rate of single atoms joining a cluster, N is the number of nucleation sites per unit volume (for homogeneous nucleation N = the number of atoms per unit volume), T is temperature, k is the Boltzmann constant and ΔG_{hom}^* is the activation energy for homogeneous nucleation (Porter and Easterling, 1992).

$$\Delta G_{\text{hom}}^* = \frac{16\pi\gamma_{\alpha\beta}^3}{3(\Delta G_v + \Delta G_e)^2} \quad (17)$$

where ΔG_v is the thermodynamic driving force for crystallization, ΔG_e is the strain energy associated with the transformation, and $\gamma_{\alpha\beta}$ is the surface energy of the nucleus-precursor interface.

In general, the activation energy for homogeneous nucleation is high, owing to a high nucleus-matrix surface energy. Consequently, nucleation from homogeneous systems is usually observed at heterogeneous sites such as interfaces or surface heterogeneities. Heterogeneities replace part of the high-energy nucleus-precursor interface with a lower energy heterogeneity-nucleus interface, thus lowering the overall activation barrier. The number of nucleation sites in heterogeneous nucleation is limited by the number of heterogeneities per unit or volume, N_{heter} or N_s . During crystallization, the phase with the highest nucleation rate controls phase formation. The criteria for a high nucleation rate are a high negative free energy of formation (ΔG_v), a low strain energy (ΔG_e), a low nucleus to matrix interfacial energy ($\gamma_{\alpha\beta}$) and a large heterogeneous nucleation site density (N_{heter}). Based only on the free energy of formation, the equilibrium phase has the largest $-\Delta G_v$ and the maximum driving force. However, strain energy differences, surface energy and nucleation site density also affect the nucleation rate and such kinetic factors can lead to the nucleation of nonequilibrium phases. The factors that influence the nucleation rate can be divided into intrinsic and extrinsic processes. Some factors are intrinsic to the equilibrium and competing metastable phases such as the respective free energies of formation, crystal density, surface energy or compositional stability range. Extrinsic factors are usually processing related, such as stoichiometry of heterometallic complexes, heating rate differences during oxide crystallization, incongruent vaporization, and the presence of dissolved impurities or second-phase impurities.

Differences in heterogeneous site density are also responsible for the formation of intermediates with a large compositional stability or for the formation of disordered intermediates before formation of ordered phases. The most common examples of

Fig. 7 Effect of BaTiO_3 seeding on perovskite $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ phase formation temperature and PMN particles seeded in a PMN-EDTA precursor. Seed concentration = $1.2 \times 10^{14} \text{ cm}^{-3}$ 100 nm BaTiO_3 particles Reproduced from Narendar, Y., Messing, G.L., 1999. Seeding of perovskite lead magnesium niobate crystallization from Pb-Mg-Nb-EDTA gels. *J. Am. Ceram. Soc* 82, 1659–1664.

undesirable second phase formation in ceramics are observed during synthesis of lead-based perovskite phases. Swartz and Shrout (1982) showed that formation of phase pure $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ from a mixture of PbO , MgO and Nb_2O_5 was impeded by the formation of an intermediate pyrochlore phase. Once the pyrochlore phase formed it was not possible to produce phase pure perovskite powder at higher temperature processing. They developed the so-called “columbite” process in which they used MgNb_2O_6 columbite powders as one of the reactants and completely avoided the formation of the intermediate pyrochlore phase. This process is used routinely for synthesizing many phase-pure lead-based perovskite powders. Incongruent volatilization during calcination is particularly a problem during synthesis of lead-based compounds like $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$. Narendar and Messing (1997) demonstrated the lowering of the synthesis temperature for $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ in a metal carboxylate gel (Fig. 7) by seeding the reaction with 100 nm BaTiO_3 particles (lattice mismatch of $<2\%$ with PMN). Lower synthesis temperature avoided PbO volatilization, and formation of the undesirable pyrochlore phase. The seeding also resulted in fine, equiaxed PMN particles like achieved in the above seeded alumina case.

Summary

Calcination and phase transformations are of critical importance for ceramics, since almost all ceramic powders are produced by such processes. The formation of phase pure ceramic powders of sub-micrometer particle size and without hard multiparticle aggregates is a primary goal of powder synthesis before firing. Seeding of ceramic transformations offers tremendous control over reaction temperatures, rates, and phase development of single and mixed oxide powders. The inherent benefits and technological simplicity of in-situ chemical seeding promises to provide a variety of new seeded ceramic materials and to establish epitaxy as an important tool for process control, as it already is in other advanced materials applications such as single crystal growth and thin film processing.

Introduction

Designing matter from atomistic to macroscopic scale is a unique attribute of chemical materials technologies, such as those based on well-defined molecular and polymeric precursors, to solve the problems arising from ceramic manufacturing with traditional powder-based technologies. They allow a precise control over the chemical compositions and microstructure of advanced ceramics and provide various possibilities towards (more or less complex) shape design that cannot be generated through conventional processes.

The Polymer-Derived Ceramics (PDCs) route represents such a chemical approach to design ceramic materials. This is typically achieved through the pyrolysis of inorganic/organometallic polymers, denoted as “preceramic polymers”, which are prepared from well-defined molecular precursors.

The main benefits of using molecular precursors and synthesizing preceramic polymers (Ionescu *et al.*, 2019) are:

- highest purity of the PDCs compared with those obtained by traditional powder technology. This is attributed to the use of precursors and polymers which allows easy purification of the reacting species by distillation or crystallization,
- high control of the homogeneity, atomic distribution and microstructure of ceramics,
- possibility to produce multi-component and hybrid (organic-inorganic) materials,
- high versatility in terms of processability because of the possibility to precisely control the physical state and rheological properties of preceramic polymers to be shaped using the same methods as for organic polymers or plastics. Alternatively, the ceramic powders (especially those with a complex composition difficult to prepare using the conventional preparative methods) derived from the preceramic polymers can be used in forming processes as performed through the conventional way of processing ceramics, *e.g.*, sintering.

A flow diagram of the single steps involved in the design of advanced ceramics from molecular precursors and preceramic polymers is shown in Fig. 1. Processing ceramics *via* preceramic polymers involves the synthesis (from molecular precursors as monomers), crosslinking (to form an infusible network) and transformation, *i.e.*, ceramization, *via* pyrolysis of these precursors at moderate temperature, typically at 800–1200°C, into amorphous covalently bound ceramics. Subsequently, an optional heat-treatment at higher temperature will achieve the crystallization of the amorphous ceramics.

The first conversion of molecular precursors into ceramics has been reported in the 1950s by Fritz and Raabe (1956) who investigated the thermal decomposition of alkyl silanes, although the initial purpose of this pioneering work was not the synthesis of SiC precursors. During the 1960s, Si-based non-oxide ceramics derived from molecular precursors and preceramic polymers (although the terms ‘preceramic polymers’ was not employed at that time) was reported by Ainger and Herbert (1960) as well as by Chantrell and Popper (1965). These works are usually considered as the pioneer studies performed in the field of PDCs. All these fundamental works led a decade later to the production of silicon carbonitride (Si–C–N) fibers by Verbeek (1974) and silicon carbide (SiC) fibers by Yajima *et al.* (1976) from polysilazanes and polycarbosilanes, respectively. These works nicely marked the beginning of the new field of PDCs and illustrated the contribution of organosilicon precursor chemistry to the preparation of non-oxide ceramics. In the intervening years, there has been much activity worldwide in the PDCs field; especially by extending the potentialities of the PDCs route toward the production of ceramics in compositions other than those containing silicon and in particular shapes, structures and textures in a way not known from other techniques.

Synthesis of Preceramic Polymers and Modification of Pre-Formed Polymers

Synthesis of Preceramic Polymers

Because of their commercial availability and low cost, chlorosilanes of the type $R_{4-x}SiCl_x$ ($1 \leq x \leq 4$) have been largely investigated as monomers for the synthesis of polysiloxanes by hydrolysis of Si–Cl bonds followed by subsequent condensation of the Si–OH intermediates to form Si–O–Si groups in polysiloxanes (Fig. 2) (Moretto *et al.*, 2000). If ammonia is used instead of water, a similar reaction – known as ammonolysis – takes place and silylamines are formed, which can condense to give polysilazanes (Fig. 2) (Kroke *et al.*, 2000). It should be mentioned that chlorosilanes can be mixed together to form blended

Fig. 1 Flow diagram for the processing of PDCs.

Fig. 2 Organosilicon precursors in the Si-C-N-O system ($R^1 = R^2 = \text{H, CH}_3, \text{CH} = \text{CH}_2$, etc.).

precursors or co-polymers (Weinmann *et al.*, 2001). In addition, they can be modified before their reaction to add specific elements to the future polymer network such as boron using, for instance, borane dimethyl sulfide as a Lewis acid-base complex (Viard *et al.*, 2018; Nguyen *et al.*, 2014). Concerning the synthesis of SiC precursors, the common approach, extensively developed by Yajima *et al.* (1976), consists of the synthesis of polysilanes (PS) *via* the Wurtz coupling method using chlorosilanes and alkali metals. The polysilanes are further converted into polycarbosilanes (PCS, $(-\text{SiR}^1\text{R}^2\text{CH}_2-)_n$) and more precisely $[-\text{SiH}(\text{CH}_3)\text{CH}_2-]_n$ upon thermolysis through the Kumada rearrangement (Fig. 2) (Yajima *et al.*, 1976; Birot *et al.*, 1995). More complex structures containing Si, C, N, and/or O in the three-dimensional polymeric network such as polysilylcarbodiimides can also be produced by non-oxidic sol-gel condensation reaction of chlorosilanes with bis(trimethylsilyl)carbodiimide $(\text{Me}_3\text{Si})_2\text{NCN}$ as illustrated in Fig. 2 (Mera *et al.*, 2013).

These reactions are not limited to organosilicon compounds. Other polymeric compositions can be envisioned by taking advantages of the reactivity of chlorine-containing precursors as molecular precursors including metal chlorides with low molecular weight compounds such as ammonia, amines, hexadimethylsilazane, hydrazines or bis(trimethylsilyl)carbodiimide to form after pyrolysis nitrides and carbonitrides. As an illustration, Eqs. (1) and (2) report specific reactions leading to metal (aluminum or titanium)-organic precursors as preceramic polymers that form aluminum nitride (Eq. (1), (Shimokawa *et al.*, 2015)) and titanium carbonitride (Eq. (2), (Lichtenberger *et al.*, 2003)) after pyrolysis.

Fig. 3 Formation of boron nitride (BN) precursors starting from boron trichloride (BCl_3) via the synthesis of trichloroborazine (TCB).

An intermediate step can be eventually included as represented in Fig. 3 with the synthesis of boron nitride (BN) precursors starting from boron trichloride (BCl_3) (Narula *et al.*, 1987).

These reactions can be assisted with catalysts and/or a low temperature treatment. However, a problem which always arises when chlorine-containing precursors are transformed into preceramic polymers using the above described strategies is the formation of HCl, liquid by-products or even salts (especially using ammonia and amine) that have to be separated from the polymer, usually by distillation (liquid by-products) or filtration (solid by-products). An elegant way to overcome this problem is to enable polymerization using reactive sites bearing by the molecular precursors such as N-H, M-H, M-C=C (M = cation such as B, Al, Si, *etc.*) by elimination, substitution or addition reactions. Such reactions can be activated by thermolysis and/or use of catalysts such as transition metal-containing compounds. These reactions represent alternative methods for the synthesis of polysilanes, polycarbosilanes, polysilazanes using hydridosilanes as molecular precursors or using chlorine-free molecules to prepare ceramics other than those produced from organosilicon precursors (Bernard and Miele, 2014a,b, Fig. 4).

Once the preceramic polymer structure is established and the synthesis done (pre-formed polymer), the process to design ceramics can be continued through the different steps detailed in Fig. 1. However, the pre-formed polymer can be further modified, chemically and/or at micro-/nanoscale, before its conversion into ceramics. This is presented in the next sections of the present chapter.

Reaction of Pre-Formed Polymers With Low Molecular Weight Species

The reactive sites, if still present in the pre-formed polymer, can be used to (1) attach low molecular weight species to the polymer backbone in order to incorporate additional elements or offer functionality to the pre-formed polymer, *e.g.*, photoresistivity and (2) perform the reaction with a second polymer (at the polymer level or during the first stages of the pyrolysis). It should be pointed out that the chemical modification of preceramic polymers (point (1)) and reaction with a second polymer (point (2)) also help to the crosslinking of preceramic polymers.

The first approach uses low molecular weight species such as Lewis acid-base complex or metal-organic species that contain one or more reactive ends capable of forming bonds by reaction with the reactive sites present in the pre-formed preceramic network. The molecules are selected on the basis of:

- (1) the nature of the element (*e.g.*, metal or metalloid) which should be added to the polymer network to form the targeted ceramics with a homogeneous distribution of the elements at atomic scale,
- (2) their supposed chemical reactivities mainly determined by the nature of the ligands they incorporate.

Most conventional structural ceramics such as binary ceramics (SiC , Si_3N_4 , BN, AlN, *etc.*) have a number of favorable performance characteristics appropriate for high-end applications. This approach that consists to chemically modify pre-formed polymers is in general investigated to access to more complex systems made of three or more elements such as highly stable amorphous structures of PDCs, *e.g.*, Si-B-C-N ceramics (Birod *et al.*, 1995; Viard *et al.*, 2017; Riedel *et al.*, 1996), ceramic nanocomposites (Bechelany *et al.*, 2014; Lale *et al.*, 2017; Bechelany *et al.*, 2017; Ionescu *et al.*, 2012; Papendorf *et al.*, 2011) and mixed crystalline solid solutions of two or more pure phases (*e.g.*, AlN/SiC (Fonblanc *et al.*, 2018)). These complex systems often exhibit dramatically enhanced properties compared to more conventional ceramics. As an illustration, using Lewis acid-base complexes based on borane (or alane) to introduce boron (or aluminum) at molecular scale via vinyl/allyl sites (*i.e.*, hydrometallation) as well as NH units (*i.e.*, dehydrocoupling) as reactive sites present in the pre-formed polymer, Si-B-C-N ceramics as highly stable amorphous ceramics and Si-Al-C-N ceramics as mixed crystalline solid solutions made of AlN and SiC phases can be generated (Fig. 5).

Using metal-organic species such as MX_z (X = ligand, z being the number of ligands attached to M) to introduce metal in the polymer network via reactive sites such as MH (M = B, Si, Al, ...) and NH groups, metal-modified silicon carbide (Cheng *et al.*, 2017; Wen *et al.*, 2014), silicon nitride (Bechelany *et al.*, 2014; Lale *et al.*, 2017; Bechelany *et al.*, 2017; Zhou *et al.*, 2015) or silicon carbonitride (Yuan *et al.*, 2014), mostly as nanocomposites can be synthesized. This can be extended to PDCs other than Si-based compositions.

Beside the addition of elements at molecular scale, this approach can be used to offer functionality to the preceramic polymer. For instance, the reaction of UV-sensitive molecules with the preceramic polymers can lead to photosensitive preceramic polymers with high ceramic yield (Nghiem *et al.*, 2007).

Fig. 4 Self-condensation of borazine leading to polyborazylene as a preceramic polymer through dehydrocoupling reactions between NH and BH reactive groups.

Fig. 5 Addition of elements to pre-formed polymers via hydrometallation (= hydroboration via the addition of B and hydroalumination via the addition of Al) and dehydrocoupling.

Blended Precursors

The second approach consists to mix different polymers. The use of polymer blends as a mixture of at least two polymers leads to the formation of composite materials (by mixing only preceramic polymers together). It should be mentioned that preceramic polymers can be also mixed with organic polymers or resin to offer functionality, *e.g.*, UV-sensitive compounds (De Hazan and Penner, 2017; Eckel *et al.*, 2016; Zanchetta *et al.*, 2016), to form hybrid organic-inorganic compounds (Augustinho *et al.*, 2016), to design porous ceramics by mixing preceramic polymers with organic polymers as sacrificial agents (*e.g.*, PMMA, polyethylene, polystyrene, ...) or nanostructured ceramics by mixing preceramic polymers with block copolymers (Lale *et al.*, 2018). Such approaches are not the subject of the present section; they will be more developed in the section devoted to processability.

This blended precursor approach has been first focused on the design of C/SiC composite materials based on the pioneering work of Interrante *et al.* (1998) from a mixture of a preceramic polymer as SiC precursor (allyl hydrido polycarbosilane, AHPCS) with pitch as C precursor. Then, it has been extended to the preparation of composites such as AlN/SiC, B₄C/SiC, and BN/SiC by simply mixing two single-component precursors (= preceramic polymers) of the desired composition (Interrante *et al.*, 2002; Paine *et al.*, 1994; Guron *et al.*, 2008, 2009; Mori *et al.*, 2006). If single-component precursors are miscible with each other or soluble in organic solvents, a molecular-level homogeneity can be achieved in blended precursors. In general, the two polymers are interacting chemically, *i.e.*, they crosslink *via* condensation or addition reactions of reactive sites present in each individual polymer at the polymer level but better during the first stages of the pyrolysis, thereby limiting the loss of the low-molecular-weight, volatile byproducts that are typically evolved during the pyrolysis of the individual polymers. This induces an increase of the ceramic yield of the pre-formed polymer. In order to increase the ceramic yield of polymers while volume shrinkage is reduced, preceramic polymers including pre-formed polymers and chemically modified polymers can be mixed with fillers at micro-/nanoscale before the conversion into ceramics.

Modification of Preceramic Polymers at Micro-/Nanoscale

As mentioned above, preceramic polymers can be modified at microscale using ceramic powders as passive fillers or metallic powders as active fillers (Francis *et al.*, 2009; Günthner *et al.*, 2012) as deeply investigated by Greil and Seibold (1992), Greil (1995, 1998, 2000) and pioneered by Seyferth (1988) and Seyferth *et al.* (1991). The first purpose of Greil's works was to investigate the limitations when producing polymer-derived bulk components. Indeed, the polymer-to-ceramic conversion (*i.e.*, polymer pyrolysis) involves a complex sequence of structural and chemical changes based on molecular rearrangements

Fig. 6 Various microstructures identified in PDCs.

associated with the release of gaseous by-products inherently inducing both weight loss and a pronounced density increase from the polymers to the targeted ceramics. The resulting high-volume shrinkage leads, if not controlled, to the collapse of the work piece that is produced. Through these reports, it has been suggested that the addition of active fillers such as metal powders to the polymers might significantly minimize the volume shrinkage (and porosity) that is developed upon pyrolysis of a polymeric green body. This is due to the reaction of fillers with the gaseous and solid decomposition products and the gases from the atmosphere (Scheffler *et al.*, 2003). Near net shape manufacturing becomes possible while the reactions allow influencing the ceramic composition by producing new phases; thus, forming in general multi-component ceramics (Torrey and Bordia, 2009). The modification of preceramic polymers at nanoscale using nanoscaled metallic powders such as titanium nanoparticles (Ti NPs) allowed nanostructuring these composites and form nanocomposites (Proust *et al.*, 2016).

After the preparation of preceramic polymers as precursors of ceramics, a heat-treatment under a controlled atmosphere at an appropriate temperature is required to achieve the conversion of preceramic polymers into ceramics.

Thermo-Chemical Conversion of Preceramic Polymers Into Ceramics

Once the synthesis of preceramic polymers has been achieved, a thermo-chemical conversion is needed to deliver ceramics in the targeted phase composition and microstructure. The conversion of the preceramic polymers into ceramics usually consists of two steps: (1) cross-linking processes at low temperatures (100–400°C) leading to infusible hybrids, *i.e.*, organic-inorganic networks; and (2) ceramization at higher temperatures by pyrolysis up to 800–1200°C leading to amorphous ceramics. Subsequent annealing at high temperatures involves the crystallization of the amorphous ceramic network and leads to (poly)crystalline ceramics. Cross-linking reduces the loss of low molecular weight components of the preceramic polymer, *i.e.*, oligomers, as well as their fragmentation processes during the further pyrolysis achieving the ceramization; thus, it increases the ceramic yield of the preceramic polymer. Cross-linking is usually thermally activated *via* addition, substitution or condensation reactions using the reactive groups that did not react at the polymer level, *i.e.*, reactive groups with latent reactivity. In addition to this classical way, it can be assisted by the reactivity of the atmosphere, *e.g.*, ammonia, chlorine, *etc.*, with functional groups, or activated by an external process, *e.g.*, electron beam, UV, plasma, The ceramization process of the cross-linked precursors involves a complex sequence of chemical and physical changes in which polymers evolve toward amorphous covalent ceramics. This occurs through various types of reactions mainly associated with the release of gaseous by-products from the reaction between the different functional groups present in the polymeric network. The evolution of gaseous byproducts involves a weight loss upon the heat treatment. The ceramic yield, represented by $(m_{\text{ceramic}}/m_{\text{polymer}}) \times 100\%$, is a subject of major importance as it decides the general applicability of preceramic polymers as ceramic precursors. The reactions which occur during pyrolysis can be investigated by means of *in-situ* characterization, *e.g.*, gas chromatography-mass spectroscopy coupled with thermogravimetric analyses and *ex-situ* methods such as solid-state NMR, FTIR, X-ray diffraction, Raman spectroscopy and elemental analyses of pyrolysis intermediates isolated at different temperatures during the conversion process. This combined characterization approach allows learning more about the mechanisms involved in the polymer-to-ceramic conversion.

Microstructural Feature of PDCs

The thermo-chemical conversion of preceramic polymers leads to amorphous, covalently bound ceramics. The amorphous character of the covalent ceramics forms a specific state which can be “isolated” or occurs as an intermediate step toward the formation of the desired crystalline ceramics composed of thermodynamically stable phases corresponding to the overall

Fig. 7 Precursors used for the synthesis of polymer-derived Si-O-C and Si-C-N ceramics and sketches of the microstructure of their derived ceramics when pyrolyzed at 1100°C in an argon atmosphere.

composition of the amorphous network. Thus, the microstructural feature of PDCs is complex and they can consist of one chemical component, *i.e.*, with a uniquely-defined chemical composition, or as a multi-component material composed of two or more chemical compounds, including solid solutions, composites and nanocomposites. Multi-component PDCs mainly consist of different phases separated from one another by distinct boundaries and represent a means to obtain novel materials with new properties. However, a multi-component material can also exist as a single phase if the different chemical components are intimately mixed (*i.e.*, miscible) at the atomic length scale forming a solid solution in the solid state. Fig. 6 reports the various microstructures accessible for PDCs.

The structures which are generated in PDCs are closely related to the temperature at which polymers have been heat-treated, to the nature of the atmosphere and to the polymer composition and structure. The pioneered works of Yajima on SiC fibers (1976) touched off a rapid development of preceramic polymers that first led to thermodynamic stable crystalline forms of ceramics made of a unique crystalline phase such as boron nitride (BN) and aluminum nitride (AlN) (Bernard and Miele, 2014a,b; Termoss *et al.*, 2009; Penckert *et al.*, 1990; Paine and Narula, 1990). Although such single-component ceramics can display differences in terms of crystallinity and crystalline quality compared to their counterparts prepared by more conventional approaches (this is particularly true for polymer-derived BN which usually displays a “meso-hexagonal” structure as defined by Hubacek *et al.* (1996)), they have a number of favorable performance characteristics appropriate for advanced component applications. However, an inherent weakness is their brittleness: they cleave along the lattice planes. A promising approach to solve this problem consists to prepare single-component ceramics composed of an amorphous inorganic network although such materials can be outside the global thermodynamic equilibrium state. Thus, by selecting element combinations for which the binding energies are derived predominantly from local covalent bonds, polymer-derived amorphous ceramics, as single-component materials, of high kinetic stability, and thus durability, can be formed. These requirements have been met by combining silicon, boron, carbon, nitrogen and/or oxygen in the same material. As an illustration, polymer-derived Si-O-C glasses, composed of a network of $\text{SiO}_x\text{C}_{4-x}$ tetrahedra (*i.e.*, SiO_4 , SiO_3C , SiO_2C_2 , SiOC_3 , and SiC_4) incorporating both Si-C and Si-O but no C-O bonds, are X-ray amorphous after pyrolysis and represent a typical example of a single-component PDC with an amorphous structure that persists up to very high temperatures (Widgeon *et al.*, 2010; Stabler *et al.*, 2018). The small amount of crystallization observed at $>1500^\circ\text{C}$ produces SiC as a result of a carbothermal reaction between SiO_2 and C (Renlund *et al.*, 1991; Bois *et al.*, 1995; Saha and Raj, 2007).

Similar observations can be made with Si-C-N materials as a second typical example of a single-component PDC with an amorphous structure that persists up to very high temperatures. The microstructure of polysilazanes-derived Si-C-N ceramics (prepared at $800\text{--}1200^\circ\text{C}$) consists of an amorphous Si-C-N matrix with tetrahedrally coordinated Si atoms bonded to either nitrogen or carbon or a mixture of carbon and nitrogen and can be therefore designated as $\text{SiC}_x\text{N}_{4-x}$ and referred to a network of mixed bond tetrahedra as for Si-O-C systems (Fig. 7). Upon further heat-treatment, Si-C-N materials remain stable up to $1400\text{--}1500^\circ\text{C}$; before starting to crystallize into Si_3N_4 that react with free carbon to form SiC. It should be pointed out that Si-C-N ceramics derived from polysilylcarbodiimides do not contain any significant concentration of mixed bond tetrahedra (Iwamoto *et al.*, 2001) as previously described for polysilazane-derived Si-C-N ceramics. Their microstructure is rather composed of nanodomains (1–3 nm in size) of amorphous Si_3N_4 and amorphous carbon (a-C) which is responsible for stability against crystallization at temperatures higher than that characteristic of the polysilazanes-derived ceramics (Fig. 7 – Widgeon *et al.*, 2012).

The incorporation of additional elements into the Si-O-C and Si-C-N (or even Si-N) systems, *i.e.*, chemical modification of polysiloxanes and polysilazanes, can lead to a further modification of their microstructure. This can first stabilize the amorphous

Fig. 8 Preparation of ceramic materials by precursor processing.

network as observed with the addition of boron to the Si–O–C and Si–C–N systems. For instance, the quaternary compositions of Si–B–C–N are found to crystallize only at temperatures as high as 1750–1800°C. This can also lead to ceramic composites (and nanocomposites) and solid solutions of two or more pure phases, especially through the modification of preceramic polymers with metal-organic species containing alkaline earth metals (Gonzalo-Juan *et al.*, 2016), first-row metals (Zaheer *et al.*, 2012a,b), transition metals as well as main group semi-metals and metals (Hojamberdiev *et al.*, 2013; Kaspar *et al.*, 2014). The incorporation of metals into Si–O–C, Si–C–N, and Si–N systems affects the phase composition and network architecture of the ceramics as well as their high-temperature evolution. Because of the different ways of incorporating metals into such systems, a large variety of materials can be synthesized from metal nanoclusters distributed in a Si–C–N matrix (Glatz *et al.*, 2010; Bazarjani *et al.*, 2011; Zaheer *et al.*, 2012a,b; Kamperman *et al.*, 2009; Schwarz *et al.*, 2015) to transition metal carbides (TMC), transition metal nitrides (TMN) and/or transition metal silicides (TMS) nanocrystals growing in a SiC, Si₃N₄, Si–C–N, or Si–C–O matrix.

Preceramic polymers do not only provide single- and multi-component ceramics as powders with excellent properties. More importantly, the polymers may be processed before their thermo-chemical conversion into advanced ceramics in more complex shapes in ways not realizable/compatible with other ceramic preparative methods. Thus, there has been intense interest by many research groups on the development of highly processable preceramic polymers as detailed in the following section.

Processability of Preceramic Polymers-Functional PDCs

Because of the possibility of controlling the cross-linking degree, the type of bonds linking monomeric units and the nature of functional groups or substituents attached to the polymer network, preceramic polymers with tailored rheological properties can be synthesized (Duperrier *et al.*, 2007; Ouyang *et al.*, 2013). Thus, the chemistry behind the synthesis of preceramic polymers can be well tailored in order to form, in a next step, as-synthesized preceramic polymers (that can contain active or passive fillers) into a desired shape. This is accomplished by a shape forming process. Thus, polymers can be highly processable as, *e.g.*, thermoset liquid compounds (thermoset because containing reactive groups with latent reactivity, *e.g.*, Si–H, CH=CH₂, B–H, N–H, ... that will react after shaping as explained above) or solid-state materials which can display thermoplasticity when heated at low temperature for applications requiring melt-processing, *e.g.*, melt-spinning.

Polymer shaping allows to produce thin parts or complex architectures such as fibers, matrices, coatings, or dense monoliths (Colombo *et al.*, 2010; Barroso *et al.*, 2019; Viard *et al.*, 2016) using common forming methods such as extrusion-based processing, impregnation/injection-based processes, dip-/spin-coating, slip-/tape-casting and pressing-based processes, *etc.* (Fig. 8). Using additive manufacturing, highly complex 3D architectures can be designed. These forming techniques can be coupled with methods for generating pore networks such as foaming processes and template-based approaches (including the use of sacrificial agents, the hard-template approaches and the self/co-assembly processing using block copolymers) to develop the porosity at various length scales (Colombo, 2008; Borchardt *et al.*, 2012; Vakifahmetoglu *et al.*, 2016) leading to micro-, meso- and/or macroporous components (Fig. 8).

After the polymers are formed, these "green" parts undergo a heat-treatment to produce a rigid, finished product. As ceramics, final materials may undergo a machining and/or polishing step in order to meet specific engineering design criteria for advanced applications. Alternatively, polymers can be directly heat-treated to form powders that can be shaped and/or sintered (Fig. 8). This

approach is very convenient to design dense ceramics when the powders exhibit a complex and tailored composition (*e.g.*, made of three or four elements) which cannot be prepared by the conventional ceramic powder technology (Bechelany *et al.*, 2015; Yuan *et al.*, 2017).

This combined approach coupling chemistry and engineering allows developing the functionality of PDCs. Thus, as-prepared PDCs can fulfill certain functions for applications requiring particular physical-chemical properties such as controlled thermal, electric, optical, magnetic, catalytic properties. As an illustration, PDCs offer a panel of applications such as reinforcing agent, thermal barrier coating systems (Barroso *et al.*, 2015), membranes (Sandra *et al.*, 2016), catalysts, electrocatalysts (de Almeida e Silva *et al.*, 2019; Swain *et al.*, 2019), solar receivers (Mazo *et al.*, 2018), or thermoelectric materials (Kousaalayla *et al.*, 2018), *etc.*

Conclusion

The present chapter has been systematically structured to give clear and detailed insights on the chemistry of polymeric precursors and transformation mechanisms for converting precursors into the solid-state polymer-derived ceramics (PDCs) structures. The PDCs route based on well-defined precursors represents a unique preparative access to ceramics with precise control over phase compositions and microstructures according to the fact that the chemical composition of the materials is controlled at molecular scale. Its main purpose is to produce ceramic materials, often non-oxidic, through the thermo-chemical conversion of suitable preceramic polymers *via* shaping (as a way of forming PDCs), curing (to further crosslink the polymer), pyrolysis (to transform the cured polymer into an amorphous ceramic) and optionally annealing (to crystallize the amorphous ceramics). The PDCs method has provided access to a vast number of Si-based ceramics including SiC and Si₃N₄ and more complex systems made of three or more elements homogeneously distributed on the atomic level (difficult to realize by conventional methods) that provide additional and improved properties as compared to those of binary systems, *e.g.*, higher stability of the amorphous network, better mechanical properties with nanocomposites consisting of ceramic nanoclusters distributed in an amorphous ceramic matrix, *etc.* Besides, the PDCs route allows accessing to conventional Si-free binary systems such as BN and AlN as well as to homogeneously mixed crystalline ceramic solid solutions and (nano)composites in various carbide, nitride, boride and silicide systems.

The industrial potential of PDCs is evident; this has been well demonstrated with the production of SiC fibers in Japan. However, to extend this potential, the process needs to be analyzed, discussed towards simplicity, scalability and cost-effectiveness. Functional properties should be also deeply investigated. With such objectives in mind, it is anticipated that there will be new opportunities for scientists in the practical use of this class of exciting materials.

Organic Additives in Ceramic Processing

Anne Aimable and Thierry Chartier, Institute of Research for Ceramics, French National Center for Scientific Research, University of Limoges, Limoges, France

Introduction

The twentieth century saw the development of new technical ceramics and has profoundly transformed the traditional techniques of fabrication. Ceramics are no-longer only clay-based materials with a natural plasticity when mixed with water, but are also based on metal oxides (such as alumina, titania, zirconia, etc.), or non-oxides (such as nitrides, carbides, borides), which are difficult to shape. Multiple ceramic processes appeared thus, using these raw materials in the form of powders, pastes and suspensions to transform them into functional ceramic products. To control their homogeneity, stability, and rheological properties, and to adjust the formulations to the process specifications, organic processing aids, such as dispersants, polymers, or surfactants, are necessarily added to ceramic powders (Lange, 1989).

The twenty first century is the one of industry 4.0, which makes the convergence of industrial production and information and communication technologies. The industry 4.0 is a new concept based on principles that are still not completely defined. One consequence is the advent of product customization and highly flexible production in smart factories. The ceramic industry is engaged in this revolution. It has already started with the arrival of innovative processing techniques such as additive manufacturing, opening new perspectives to get on-demand materials, finer resolution, original shapes and more versatility (Zocca *et al.*, 2015). The current challenge concerns the discrete nature of raw materials, ceramic powders being heterogeneous, often with agglomerates, abrasive, and with a high melting temperature.

This chapter presents the basis of ceramic formulations emphasizing the specific actions of organics to adapt the raw powder properties to ceramic processing requirements. More attention is paid to the triptych dispersant, binder and plasticizer, which confers fundamental properties, i.e., stability, adapted rheology with low viscosity at high solid loadings, and green cohesion. The new developments done this last decade are emphasized, either on new formulas, or on a better understanding of the organics action and interactions. Finally some challenges are stated for the future of ceramic formulations, which will come along the developments of new manufacturing methods, in a century where new rules will be imposed by a higher environmental awareness.

Formulation Concepts for Ceramic Processing

Traditional ceramics, as potteries manufactured thousand years ago, are made up of clays, because these materials are naturally plastic when mixed with water. Actually most ceramic powders are inherently difficult to handle and shape, because of a lack of cohesiveness and plasticity. Forming techniques commonly employed for metals and polymers, e.g., deformation methods, melt casting, or machining operations, are unsuitable. In order to develop technical and advanced ceramics, the strategy consists in employing organic processing aids in order to adapt the raw material to the forming technique specifications (Reed, 1995). Organics are necessary to provide to ceramic mixtures optimal properties for the forming process chosen, generally in terms of stability and rheology (Shanefield, 1999).

In a classical approach (Lange, 1989; Haussonne *et al.*, 2005), a ceramic material is the result of five processing steps, which all affect its final properties (Chartier, 2007):

- (1) Powder selection: ceramic powders can be prepared by different synthesis methods, or obtained by chemical treatments of natural ores. Their properties are adapted to the process or the final application by chemical or physical treatments, generally classification, grinding, milling, and dispersion.
- (2) Formulation: this step consists in the definition of the nature and amount of solvent and organics added to the powder, in order to confer to the ceramic mixture the required properties to the shaping process. This step most often requires an optimization.
- (3) Shaping process: this step allows to give a shape to a ceramic powder, feedstock or slurry through the use of a specific technique.
- (4) Low temperature consolidation: drying.
- (5) High temperature consolidation: organics removal (debinding) and sintering.

Shaping processes can be classified according to the nature of the ceramic mixture that can be in a dry state (e.g., for uniaxial or isostatic pressing), in a plastic state (for extrusion or injection), or in a liquid state (e.g., for slip casting or granulation). The nature and amount of organics differ drastically between the different processes, from only a few percent of the volume of the final mixture (e.g., for uniaxial pressing), to 50% of the volume (e.g., for injection), as summarized in Table 1.

The role of these additives is also to confer the desired cohesion and plasticity to the green body. Drying is a critical step which can reveal problems present in the formulation such as inhomogeneity, segregation, sedimentation, or lead to cracks due to capillary stresses associated to the inherent fragility of ceramics, which may be partially solved by an appropriate use of organics.

Table 1 Classification of ceramic formulations depending on the forming process

Formulation			Ceramic forming process	
Ceramic mixture	%vol of powder	%vol of solvent and organics	Classical	Additive manufacturing
Powder	>90	<10	Pressing (uniaxial, isostatic, etc.)	SLS (selective laser sintering)...
Paste or feedstock	50–70	30–50	Extrusion, injection molding	Robocasting,...
Colloidal suspension	15–50	50–85	Slip/gel/coagulation casting, tape casting, granulation...	Ink jet printing, stereolithography, etc.

Table 2 List of nature and functions of organic additives used for ceramic processing

Nature of organic additives	Function
Dispersants	Improve stability, state of dispersion and adjust rheological behavior of suspensions
Binders	Improve green strength
Plasticizers	Improve flexibility and handling of green bodies
Lubricants	Decrease frictions and improve mold release
Wetting agents	Decrease surface tension of liquids and improve wettability
Humectants	Slow down drying
Antifoaming agents	Prevent foam formation or destroy foam
Fungicides, bactericides	Improve stability with aging

Finally, these organics, which are necessary during the formulation and the shaping steps, must be completely removed before the sintering step. They are usually released by pyrolysis at moderate temperature (200–600°C), below the temperature of densification of the material. The debinding remains a critical step in the elaboration of a ceramic part. Therefore the choice of the nature and amount of organics also depend of parameters such as the temperature and time of pyrolysis, the chemical elements remaining after calcination which may affect the densification and the final properties (such as alkali, sulfur, carbon, etc.) and cost.

General Use of Organics for Ceramic Processing

Types of Organic Additives

Organic additives for ceramic processing provide multiple functions (Pugh and Bergström, 1993), most of them being reported in Table 2.

The stability of the ceramic base system and a satisfactory state of dispersion are generally difficult to obtain without the use of a dispersant, which is compulsory in most ceramic formulations. Dispersants avoid particle agglomeration, and improve rheological behavior of suspensions (Lewis, 2000; Bergstrom, 2001).

Binders and plasticizers are also present in most ceramic formulations, as it is very difficult to give cohesion, avoid cracks together with a good handling of green bodies from ceramic powders only.

The other additives listed are less common and really depend on the processing method and the powder. For example, ink-jet printing imposes drastic specifications to the formulation of ceramic suspensions in terms of surface tension for instance, in order to be ejected through very fine nozzles below 50 µm in diameter, and in terms of drying of the deposited droplet. Therefore formulations include dispersant, binder, plasticizer, humectant and surfactant (Magdassi, 2010). Extrusion process will impose the use of a lubricant to limit the frictions with the metallic parts of the machine, as well as a defoaming agent to eliminate air bubbles introduced during the aqueous feedstock preparation.

A focus on the action of dispersant, binder and plasticizer, and the main molecules used for these functions, is presented in the following.

Dispersants

The role of dispersants is to maintain a high degree of stability of ceramic powders in liquid or organic medium, i.e., to avoid their agglomeration, coagulation or flocculation, and finally their sedimentation.

Dispersion of ceramic powders in liquids is the result of three stages. The first one is wetting, in which the liquid phase wets and spreads on the powder external surface, and where solid/gas interfaces are replaced by solid/liquid interfaces. The second stage consists in deagglomeration, by breaking up aggregates and agglomerates, in order to form primary particles, using a mechanical action such as dispersion or milling. The last stage is the stabilization when the primary units remain dispersed through the liquid medium.

Table 3 Dispersant stabilization

<i>Dispersant stabilization</i>		
<i>Electrostatic</i>	<i>Steric</i>	<i>Electrosteric</i>
		
Carboxylic acid, sulfate, sulfonate, phosphate, etc.	Non-ionic polymer, oil, fatty acid, ester phosphate, etc.	Polyelectrolyte (polyacrylate, polymetacrylate, polysulfonate, etc.), polyimine, etc.

In the last stage, particles are subject to different interactions: attractive forces of Van der Waals, repulsive forces resulting from their surface charge, Brownian motion, gravitational effects. For colloidal particles, the problem of the stabilization is treated by the DLVO theory (Derjaguin and Landau, 1993).

Dispersants are surface-active chemical agents allowing either electrostatic and/or steric repulsions between primary particles. The selection of appropriate dispersants depends on the nature of the chemical surface of particles, and the nature of the solvent (Table 3).

Steric stabilization

Steric dispersants are oligomers, long-chain polymers or block copolymers, which adsorb at the surface of ceramic particles and create a physical barrier avoiding particles to approach at a distance where Van der Waals forces are influent (a few nanometers) (Napper, 1983). To be efficient, such species should contain anchoring groups to adsorb on the particle surface, and have a good solubility in the solvent to form the largest layer of repulsion. However, if the polymer can adsorb to more than one particle at the same time, the polymer will hold the particles together, and give rise to the so-called bridging flocculation. This effect is generally observed with a strong adsorption from the polymer of high molecular weight. In the case of non-adsorbed polymer, an attractive force is created if the polymer is evicted from the region between two approaching surfaces. A high concentration of polymer creates an osmotic pressure difference resulting in the so-called depletion flocculation. With a good solvent compatibility, polymers will extend their chains and form long tails, whereas with lower compatibility, they will roll and form loops to minimize solvent interactions, and thus their effect. Therefore, non-charged polymers are used in organic solvents (polyethylene glycol...), as well as organic molecules of smaller size such as phosphate esters, fatty acid esters, oils (Menhaden fish oil), etc., whereas polyelectrolytes are used in aqueous solvent.

Electrostatic and electrosteric stabilization

All materials spontaneously acquire an electrical surface charge when they are in contact with a polar medium like water. In the case of ceramics, which present a metal oxide surface (M–OH), surface charges are the result of an ionization of surface groups and is very dependent of pH and electrolyte concentration (James and Parks, 1982).

The role of electrostatic dispersants is to enhance particles surface charge by adsorbing charged molecules. Electrostatic stability is generally correlated to a high zeta potential value (Vallar *et al.*, 1999). Acidic molecules stabilize basic surfaces (such as alumina), and basic molecules stabilize acidic surfaces (such as silica). For example, alumina or zirconia suspension is stabilized with inorganic acids such as nitric acid, and organic acids such as acetic acid which adds a small steric barrier (Bowen *et al.*, 2002; Hanaor *et al.*, 2012). Silica or silicon carbide suspension is stabilized by inorganic bases such as ammonia, or by organic bases such as TMAH (tetramethylammonium hydroxide) (Li *et al.*, 2004).

Polyelectrolyte dispersants are widely used in aqueous-based formulations. These are polymers which contain ionizable groups such as carboxylic acids, sulfates or sulfonic acids. Polyanions are much more widely used, whereas positive charges are almost essentially obtained with polyethylene imine (PEI) which contains amino groups (Baklouti *et al.*, 1997b; Boufi *et al.*, 2002). The most employed polyelectrolytes are the derivatives of polyacrylic acid such as Darvan C–N from Vanderbilt Minerals, and Dolapix from Zschimmer & Schwarz. Polyelectrolytes combine both steric and electrostatic effects, sometimes called electrosteric effect, leading to very high performances at low concentration of polymer. Their adsorption and conformation are correlated to the chemical and physical properties of the powder and the solvent (pH and ionic strength). Adsorption is favored when polyelectrolyte species and particle surface carry opposite charges. For example, polyacrylate (PAA) adsorption onto alumina surfaces is doubled at pH 6 compared to pH 10, and saturation is observed very rapidly at pH 10 (Bowen *et al.*, 2005). Moreover PAA conformation is very different at pH 6 and pH 10: many adsorption sites are present at pH 6 leading to a flat conformation, whereas at pH 10, the number of adsorption sites is few leading to a brush-like conformation.

Dispersants of lower molecular weight may have advantages over such polyelectrolytes thanks to a lower cost, higher adsorption capacities, or by avoiding bridging effects. Small carboxylic acids such as citric acid, oxalic acid, formic acid, etc., are very effective electrostatic dispersants for aqueous suspensions of Al₂O₃, TiO₂, or ZrO₂. More recently, new molecules proved a very high efficiency for the dispersion of alumina nanopowders, allowing high solid loadings at low concentration of dispersant. This is the case of 2-phosphonobutane-1,2,4-tricarboxylic acid (PBTCA), introduced in the form of a sodium salt (PBTCA), and which presents an “umbrella” structure with three functional –COO[–] groups (Penard *et al.*, 2005). This molecule can be grafted at the oxide surface thanks to the phosphonate group. Its performance is close to 4,5-dihydroxy-1,3-benzenedisulfonic acid (Tiron)

added as a disodium salt. This last molecule adsorption is due to the formation of an inner sphere complex between the alcohol groups and the metal ion of the alumina surface, while the two functional $-\text{SO}_3^-$ groups bring a high negative charge.

Clays were traditionally stabilized with inorganic salts such as sodium metasilicate (Na_2SiO_3), sodium orthosilicate (Na_4SiO_4), sodium carbonate (Na_2CO_3), or some mixtures of those salts (like Dolaflux Zschimmer & Schwarz). Some new defloculants have recently appeared showing a higher efficiency, by coupling a better understanding of the stabilization mechanisms and the physico-chemical properties of the raw powders (Carty *et al.*, 2000). Actually, these materials are phyllosilicates, presenting both silica-like and alumina-like surfaces. The efficient dispersants are the same as those used for alumina in technical applications, despite the dual nature of these materials. Therefore, polyelectrolytes such as polyacrylic acid (PAA), polymetacrylic acid (PMAA) or polyphosphates like sodium hexametaphosphate (HMP) are now classically used in clay formulations (Carty *et al.*, 2000). Another class of dispersant for these materials are block copolymers, with a block bearing anionic groups such as acrylates, and another block inducing steric hindrance.

Finally, even if electrostatic stabilization is closely associated to aqueous solvents, electrostatic effects should not be neglected in non-polar media. In electrolyte with moderate dielectric constant such as low molecular weight alcohols, amines, aldehydes or ketones, there is a low degree of ionization leading to charging mechanisms similar to those present in water, with a lower charge density. For solvents with a very low dielectric constant (alkanes, alkenes, aromatics, etc.) some dispersing agents are able to give a particle surface charge through an electron-donor or acid-base mechanism (Pugh and Bergström, 1993). Therefore acidic polymers (e.g., PVC) or basic polymers (e.g., PMMA) are very effective dispersants in non-aqueous media.

Binders and Plasticizers

The role of binders is to enhance the strength of green ceramic bodies, whereas plasticizers bring flexibility and malleability. These additives are generally polymers. Binders often present a higher molecular weight than plasticizers (generally 10^4 – 10^5 g/mol for binders, and 10^2 – 10^3 g/mol for plasticizers). Plasticizers have generally a high degree of solvent power for the binder. Their action results from an adsorption on the polymer chains to reduce the valence forces between them. This leads to a softened polymer, with enhanced flexibility and a lower glass transition temperature (T_g) (Baklouti *et al.*, 1997a).

The binding action is the result of a physical adsorption on the surface of ceramic particles. These polymers must present a good affinity for ceramic surfaces through electrostatic interactions or hydrogen bonding. As a consequence, their adsorption can compete with dispersant, leading sometimes to a desorption of the dispersant in time, and a loss of stability in the final formulation. That is why the protocols of formulation have to be carefully defined. For example, the order the additives are introduced with the ceramic powder is crucial: if the binder is present first, all adsorption sites may be occupied and no dispersant may adsorb (Marie *et al.*, 2017). The successive treatments applied to the suspensions or pastes have to be carefully considered. If a milling treatment is applied, desorption of the dispersant may occur. Moreover, the milling treatments in general may break the chains of the polymers and modify their action.

Binders and plasticizers must be soluble in the solvent. To be water soluble, organic binders have to contain polar groups. These chemical functions develop intermolecular bonds that often make them insoluble. To avoid this effect, they present side groups to inhibit intermolecular interactions. This is the case with poly(vinyl alcohol) (PVA), which is a classical binder for ceramic systems in aqueous solvent. PVA is insoluble in water and presents 12%–20% of acetate groups to render it soluble. Cellulose is modified in the same way by replacing $-\text{OH}$ groups by methyl, hydroxyethyl, carboxymethyl or hydroxypropyl side groups. In non aqueous systems, the most common binders used are poly(vinyl butyral), poly(methyl methacrylate), polystyrene, ethylcellulose, paraffin, wax, etc. Phthalates are excellent plasticizers in organic solvents.

Binders have a significant effect on viscosity, depending on their concentration. Examples of low-viscosity polymers are Arabic gum, lignosulfonates and dextrin. Low to medium-viscosity polymers include poly(vinyl alcohol), poly(vinylpyrrolidone), poly(ethylene oxide), acrylic and poly(ethylene imine). Medium to high-viscosity polymers include modified cellulose and alginate. The viscosity is also impacted by molecular weight, as well as polymer conformation. If the chains of the molecule are deployed and extended, it will confer a higher viscosity to the formulation than if they are curved and rolled. Furthermore a solution of binder can gel, by physical or chemical bonding between the polymer molecules. The formation of the gel can be induced by a thermal action (heating or cooling), or through the addition of a chemical agent.

Organic binders that are insoluble in water can be added as emulsions or latexes. For example, waxes can be used in aqueous systems through the use of an emulsifying agent. A latex consists of a stable concentrated polymer colloidal dispersion in water. In ceramic formulations, acrylic latexes are predominant (Pagnoux *et al.*, 1998). Their great advantage is that the viscosity remains low even at high solid loadings, reducing the amount of solvent to be removed during drying. The action of this type of binder is based on a different mechanism than classical polymers. When water evaporates during the drying stage, polymer colloids coalesce to yield a binding film that encapsulate ceramic particles to give cohesion and strength (Kiennemann *et al.*, 2005). With a high T_g , the latex will give strength to the ceramic material, whereas with a low T_g (below ambient), it will provide flexibility. Therefore, some different latexes can be combined to obtain the required green strength.

Other Additives

Dispersant, binder and plasticizer constitute the compulsory triptych of the organics used in ceramic formulations to get an adapted behavior of a suspension, a paste or a ceramic powder. However some other additives can be added to address specific requirements.

Wetting agents may be added to ceramic formulations in order to lower the surface tension of the suspension, leading to a better spreading on surfaces during the processing steps or in the molds. These are generally surfactants possessing a hydrophilic head and a hydrophobic tail.

The presence of many organics and especially surfactants may cause the stabilization of air bubbles, in the form of micro-bubbles or surface foam, which cause residual porosity in the final material. Defoamers are chemicals that prevent foaming, or destroy any foam produced during the processing steps. Generally a defoamer is insoluble in the foaming medium and has surface active properties. Its action results from an affinity to the air-liquid surface to destabilize the foam lamellas, leading to the rupture of the air bubbles. A large variety of defoaming agent exists. The main products are oil-based defoamers containing waxes such as paraffin, esters or fatty alcohols, and silicone based defoamers, which can be found as oils or water-based emulsions. The last generation are molecular defoaming agents, which interact with the other surfactants in the formulation to prevent them from stabilizing the foam.

Lubricants are used to minimize the friction, heat and wear of mechanical parts in contact with the ceramic system, which can lead to pollution of the ceramic material. Lubricating oil is the most commonly used lubricant because of its wide range of applications. Mineral oils are refined from naturally occurring petroleum. Synthetic oils are manufactured polyalphaolefins, which are hydrocarbon-based polyglycols or ester oils.

Humectants are hygroscopic substances used to keep moisture, and slow down drying. Their hygroscopic power comes from the presence of hydroxyl groups ($-OH$) or other hydrophilic sites (amines...) that can interact through hydrogen bonding with water molecules. Common humectants are glycerol, propylene glycol or sugars such as sorbitol.

Fungicides or bactericides may be used to kill parasitic fungi or their spores and bacteria, or at least limit their development, in order to increase the shelf life of formulas, especially for water-based systems.

Therefore ceramic formulations may contain many different organic additives. Some of them present sometimes a dual effect: dispersant and wetting agent, plasticizer and lubricant, etc. However ceramists and formulators are well encouraged to limit their number and their amount as much as possible, to limit the cost, the potential unfavorable interactions between them and problems during debinding.

New Challenges for Organics in Ceramic Formulations

The bases of ceramic formulations are now well-established. Current researches are performed on the introduction of new products, with more efficiency at lower cost, with a lower environmental impact, or with specific functions addressed by the arrival of new shaping processes.

Copolymers Acting as Dispersant and Binder

Polymeric binders used in aqueous formulations generally present interactions of lower intensity compared to the electrostatic interactions typically encountered for dispersants, mainly polyelectrolytes. This induces an increase of the viscosity of the suspension due to a large amount of binder remaining in solution, and a heterogeneous distribution of the organics in the green material, for instance in dry pressing of spray-dried granules. The use of a copolymer acting both as a dispersant and as a binder constitutes an attractive solution. Copolymers of sodium acrylate and of vinyl hydroxide have been synthesized with different contents of acrylate groups corresponding to the dispersing block. They were used for the spray drying of alumina suspension (Romdhane *et al.*, 2004, 2007). Adsorption takes place due to carboxylic groups that anchor the polymer chain on specific surface sites, namely $Al-(OH_2)^+$. On one hand, the amount of carboxylic groups controls the effective charge density of the particle surface and thus the dispersing effect. In another hand, the hydroxyl vinyl groups promote a loop-like adsorbed configuration, the thickness of loops increasing with the content of such groups, and thus the binding effect. Many advantages are obtained from these organics. These copolymers have a low T_g , and thus no plasticizer is needed. Because they are adsorbed at the particle surface, no migration is observed during the spray-drying, leading to a more homogeneous distribution in the final granule. As a consequence a higher density is measured on pressed pellets prepared from these granules, as well as a more homogeneous microstructure and much higher mechanical properties.

Organic Templates for Porous Ceramics

The highest density is the general target for most ceramic applications and porosity is generally avoided. However, an increasing demand of porous ceramics have appeared in the last decades, especially for environments where high temperatures, extensive wear and corrosive media are involved. Different strategies exist to produce porous ceramics, depending on the pore morphology, the porous volume fraction, and the pore size, which were reviewed by several authors in the last years (Imhof and Pine, 1997; Studart *et al.*, 2006; Holzwarth and Ma, 2011). "Large templating objects such as colloids, microspheres and emulsions are exploited to create macroporosity at different length scales, from submicron to several hundred micrometers and millimeters, whereas mesopores are obtained via supramolecular structures formed from self-assembly of surfactants, and micropores can be generated by the templating effect of single molecules", cited from (Colombo *et al.*, 2010).

One strategy to create macroporosity is the replica method, based on the impregnation of a cellular structure with a ceramic suspension or a precursor solution, in order to produce a ceramic exhibiting the same morphology as the original porous material. Synthetic templates, such as polyurethane foams, are the most widely used, whereas some natural templates can also be found (wood or coral...) (Studart *et al.*, 2006). Another technique is the use of a sacrificial phase, also called porogen or pore-former agent, which is dispersed into the ceramic matrix, and leads to porosity after pyrolysis. Many different organics can be found in the literature, such as synthetic polymers (PVC, polystyrene, PMMA beads, etc.) (Tang *et al.*, 2004) or natural products (cellulose, starch, gelatin, etc.).

Mesoporosity concerns pores below 50 nm, and is obtained through the condensation of ceramic precursors around a molecular template made of surfactants or block copolymers (Wan and Zhao, 2007; Cai *et al.*, 2011). Surfactants are interesting molecules which form micelles by self-assembly leading to original architectures. The mesoporous material is obtained via the EISA effect (Evaporation Induced Self-Assembly), after elimination of the solvent and the organic template (surfactant or polymer). The mesoporosity is determined by the nature of the organic, its concentration, and its interaction with the ceramic precursor. This strategy, by using a strong coupling between inorganic and organic chemistry, is falling into the field of hybrid materials, which represents also a novel branch of developments for ingeniously designed ceramic materials (Judeinstein and Sanchez, 1996; Sanchez *et al.*, 2005).

Organics for Innovative Processing Methods

In the last twenty years, some new shaping processes have been developed in the domain of traditional and technical ceramics. It is first explained by the arrival in mass of powders with finer particle sizes, in the colloidal domain ($< 1 \mu\text{m}$), along with a better understanding of the fundamental mechanisms underlying particle–particle interactions. The “colloidal processing” concept appeared, which is based on the manipulation and control of the interparticle forces in suspensions, in order to remove heterogeneities and to optimize the suspension properties (Lewis, 2000; Bergstrom, 2001). At the same time, there has been a growing interest for additive manufacturing techniques to produce 3D ceramic parts with complex architectures. Specific organics accompanied these evolutions, with some examples reported below.

Colloidal granulation

Colloidal granulation is an original shaping process leading to spherical granules of millimetric size directly in suspension from a diluted system of colloids. It was obtained first by heterocoagulation of two materials, e.g., alumina and silica, to produce dense spheres (Garcia-Perez *et al.*, 2007). These primary systems contained no organics, and thus many defects were observed, attributed to a low compaction of the green material and a high migration rate of the particles during the drying step (Pagnoux *et al.*, 2009). Another system studied was made of titania nanoparticles dispersed with a polyelectrolyte, the poly(sodium 4-styrenesulfonate) (PSS). In a very small range of conditions, some primary agglomerates could be formed thanks to an attractive interaction between Ti-OH_2^+ surface groups and $-\text{SO}_3^-$ functions of the adsorbed polymer, and then inducing a coalescence through a bonding effect (Pringuet *et al.*, 2008). By adding a second polyelectrolyte of opposite charge, the chitosan (cationic, whereas PSS is anionic), an electrostatic interaction between the two polymers occurred in situ, leading to the formation of submicronic organic filaments binding titania agglomerates to each other, and extending the experimental range of conditions to form the millimetric spheres (Pringuet *et al.*, 2011b). The use of these organics also present the advantage of adding plasticity inside the spheres, improving the drying step by allowing colloidal particles to move and rearrange when water is removed. Finally, some organic colloids such as a latex of polystyrene could also be added leading to the formation of porous granules presenting a very well-ordered microstructure, with multi-scale porosity (Pringuet *et al.*, 2011a).

Direct casting forming methods

Direct casting forming methods are able to create near-net-shape products and components with more complex shapes. The concept is to transform a fluid suspension to a stiff gel, in order to retain the homogeneous state of the dense slurry (Sigmund *et al.*, 2000). The great advantage of these methods, compared to more classical shaping processes, is the minimization of heterogeneities and density gradients. The physical or chemical processes responsible for the formation of a solid green body may vary, but all methods require a well-dispersed suspension with very high solids loading and a low viscosity to facilitate the mold-filling process. The preliminary step of powder dispersion must be particularly optimized with an appropriate use of dispersants. In a second step, the green body formation is obtained through the formation of either physical or chemical bonds between the particles or some species introduced in the dispersion.

Physical gels rely on the formation of physical bonds which is mainly achieved by manipulating the interparticle forces between the particles in suspension to become attractive (Gauckler *et al.*, 1999). This can be achieved by changing pH or increasing salt content, whereas sterically stabilized systems can be flocculated by changing the solvency of the adsorbed polymer (Bergström and Sjöström, 1999). pH may be modified by addition of an electrolyte (HCl, or $(\text{C}_2\text{H}_5)_4\text{NOH}$), but a better approach is to use a reaction that produces the desired pH or salt change in-situ. Examples of such reactions are thermally activated decomposition of urea, formamide, acetamide, or hexamethylene tetramine, which change the pH from acidic toward neutral by slowly forming NH_3 at 60–80°C (Sigmund *et al.*, 2000). Hydrolysis of esters or lactones yields carboxylic acids, changing pH from alkaline toward neutral. An increase in salt concentration is induced by the decomposition of urea, which can also be catalyzed by an enzyme,

urease (Gauckler *et al.*, 1999). Hydroxylaluminum diacetate decomposes as the temperature increases to release acetate and aluminum ions (Laucournet *et al.*, 2000).

Chemical gels are obtained by the formation of permanent chemical bonds between either the particles or some species in the dispersion. Typical examples are the formation of a percolating polymer network by polymerizing a monomer in the slurry, or the gelation of dissolved polymers. Vinylmonomers and cross-linking agents are mainly used in this process (Young *et al.*, 1991; Omatete *et al.*, 1997). Because they undergo a free-radical chain polymerization reaction, the setting is very rapid. Natural gels can also be used such as gelatin or alginates (Yang *et al.*, 2011), with much lower toxicity (Janney *et al.*, 1998). Cross-linking of polymers or proteins is also reported, for example cross-linking of PVA with Ti^{4+} (Morissette and Lewis, 1999).

Additive manufacturing of ceramics

Additive Manufacturing (AM) processes are numerical technologies used to fabricate 3D parts directly from their 3D Computer Aided Design (CAD), without specific tooling. AM involves the addition and/or bonding of materials to form objects, and is based on a manufacturing procedure with a construction layer upon layer.

These technologies offer advantages such as a reduced cost for the fabrication of prototypes or of short-run production, a reduced time to market, the process of complex shapes and specific architectures impossible to obtain by conventional routes, to be able to improve properties or to introduce new functions. AM is more and more used to directly fabricate useful functional parts or functional prototypes to test forms, fit and function. Another important application is the concept modeling and prototyping (Chartier and Badev, 2013).

Several processes have been developed for the additive manufacturing of ceramic parts, based on powder, suspension, paste, or tapes systems. The majority of these processes require the use of organic additives.

Stereolithography involves the selective photopolymerization of a reactive system. The reactive system consists in a dispersion of ceramic particles in a curable monomer/oligomer (e.g., acrylates) with the help of a dispersant. A photoinitiator (benzophenone derivative) allows to cure the system and a diluent (e.g., 1,6-hexane diol diacrylate (HDDA)) is used to decrease the viscosity (Badev *et al.*, 2011).

Robocasting or Fused Deposition Modeling processes consists in the extrusion of a filaments through a nozzle. FDM used a thermoplastic (e.g., waxes) ceramic system that immediately hardens after being extruded from the nozzle and bonds to the layer below. Robocasting consists in extrusion of a filament through a nozzle. The feedstock contains, as for the extrusion process, a dispersant, a solvent, a binder and a plasticizer (Cesarano, 1998; Lewis *et al.*, 2006).

Inkjet printing consists in the deposition of small droplets (typically about 50 μm diameter) of a ceramic suspension or of precursors, generally by means of piezoelectric nozzle. The ejection of the droplet (viscosity, surface tension, etc.) and its drying just after deposition require low concentrated suspensions of ceramic particles containing a dispersant, a binder, a plasticizer, a surfactant and a humectant (Lejeune *et al.*, 2009).

Binder jetting involves the jetting of binder (aqueous solution of PAA, PVA, or PEG) to selectively consolidate a deposited layer of powder. A jetting head deposits a binder to bond ceramic particles in the defined pattern (Sachs *et al.*, 1990).

Towards Low Environmental Impact (“Green”) Formulations

Most of the organics introduced in ceramic formulations are chemical products coming from the petroleum industry, which may present risks for the operator health or the environment. From a more general point of view, there is today a growing manifest conscience of the negative impact of some human activities on the energetic and raw materials resources, as well as the pollution. Therefore there is a tremendous demand for low-impact and sustainable chemicals and processes, in order to preserve living and energetic resources.

In this context, researchers propose some substitutes to the traditional organic additives coming from petrochemicals via the use of biosourced additives, which present less risks for the operator's health, and are renewable products.

Lignosulfonates have been identified as renewable alternatives to classical polyelectrolytes used as dispersants in ceramic formulations. Lignosulfonate macromolecules are negatively charged when dissolved in water. It has been shown that ammonium lignosulfonate extracted from the maritime pine of Landes (France) is an effective alternative to polymethacrylate for alumina dispersion, leading to similar performances in terms of zeta potential and rheological behavior (Marie *et al.*, 2017). Few other organics have been reported as ceramic powder dispersant in the literature, such as cellulose derivatives (methylcellulose, ethyl hydroxyethyl cellulose (Schlordt *et al.*, 2013)).

Naturally occurring polysaccharides are biopolymers and a wide variety of them have been employed for various material applications (Kamel *et al.*, 2008; Umoren and Eduok, 2016), especially as binders: gums, carboxymethyl and hydroxyethyl cellulose, starch, pectin, substituted or modified chitosans, carrageenan, dextrin and cyclodextrins, alginates, etc. Different biosourced binders have been recently used in alumina formulations: a pectin gel for tape casting (Marie *et al.*, 2017), and a psyllium gel for micro extrusion (Bouret *et al.*, 2018) which showed high performances.

One limitation to the use of these biopolymers is that they are often subjected to preliminary treatments which may impact the environment. For example cellulose is not water-soluble, therefore cellulose derivatives are synthesized by chemical transformations such as substitution of hydroxyl groups by methoxyl groups using caustic soda solution. Chitosan is obtained by a reaction of deacetylation in strong alkaline conditions of crustacean shells. Another limitation is the reliability and the reproducibility of

these products in term of purity, and intrinsic properties such as concentration of active matter, rheology, etc. But the diversity of such products and their high modulation capacity open very large perspectives for a more environmental-friendly approach of ceramic formulations.

Powder Mixing and Grinding Processes for Ceramics

David Houivet and Jérôme Bernard, Normandy University, UNICAEN, LUSAC, Caen, France

Introduction

Ceramics are prepared from inorganic raw materials in the form of powder grains. During sintering, due to the action of diffusion mechanisms, grains weld together and porosity between grains is eliminated leading to material densification. The raw materials have therefore a direct influence on the final properties of ceramics. In order to control these properties, a selection of the raw powders with adequate characteristics is required and some post-treatments can be applied to obtain the desired characteristics.

It is commonly accepted that the initial powders used for technical ceramics, both in the laboratory and in industry, should:

- (1) Possess a high chemical purity, often exceeding 99%. Care must be taken to limit the pollution generated by the adaptation processes, particularly grinding;
- (2) Be fine. Indeed, the reactivity of powders in the solid process is directly linked to the size and particle size distribution. The finer is the powder, the higher the specific surface area, which increases the energy of the system and promotes diffusion reactions in the solid sintering process, and which leads to a reduction of sintering temperature and time. As a result, micron- and sub-micron sized powders will be sought. The classic grain diameter range is from 10 μm to 10 nm, corresponding to specific surface areas between 0.1 and 100 m^2/g ;
- (3) Be homogeneous and well dispersed, without presence of aggregates or agglomerates. In the case of a mixture of powders of different natures, it must be intimate and as homogeneous as possible to reduce the diffusion distances during solid state reactions or during reactive sintering. In addition to the gain of energy, it is wished that the formation of secondary phases resulting from a localized stoichiometry different from the rest of the mixture can be avoided and a well controlled and homogeneous microstructure of the ceramic can be obtained.

A first major technological step in the manufacture of a ceramic is the mixing and grinding of raw materials, or calcined powders, in order to adapt the powders to the desired characteristics. This stage can be carried out in a dry or wet environment.

At the beginning of the 19th century, Brongniart (1844) pointed out the difficulty of working "pastes", such as siliceous materials "which were difficult to work into the bottom of the water". Empirical solutions included adding vinegar, "rot" or even swampy water. The porcelain and earthenware treaty of the 1950s (Haussonne, 1954) is more pragmatic and recommended adding acetic acid or ammonia to keep the powder in suspension. Finally, more scientific considerations (Jouenne, 1980) were published with first studies of the dispersion of the slurries considering the pH value.

It appears therefore that in order to master this mixing and grinding stage, it is necessary to have a good understanding of slurry dispersion. Some notions are essential such as knowledge of the physico-chemistry of powder surfaces, of the dispersion behavior, of the additives which allow to control both the attractive or repulsive forces arising between particles and which will modify the rheological behavior of these suspensions. This will be the first part of this chapter.

As the electronic properties of ceramics are often very sensitive to dopants, special attention must be paid to the contamination that may be brought about by the grinding process. As it will be seen in the various applications described below, a compromise will often have to be made between the positive effects of grinding, which makes it easier to achieve better densification, more homogeneous microstructures, or the formation of pure phases, and a negative aspect brought about by polluting elements. These aspects will be discussed in the second part of the chapter through a short description of two major studies.

State of the Art

This chapter is devoted to the necessary knowledge to understand the phenomena occurring during slurry dispersion and mixing and grinding steps occurring in ceramic processing. It presents a synthesis of several books and review articles (Haussonne *et al.*, 2005; Funk and Dinger, 1994; Parfitt, 1981; Dinger, 2002; He *et al.*, 2004; Vallar *et al.*, 1999).

Properties of Slurries and Pastes

In order to adapt the characteristics of powders to the desired parameters (in particular average diameter, or specific surface area), a cycle of mixing and grinding of the powders is necessary. The most efficient methods require this operation to be carried out in a liquid medium, in the form of slurry. The aim is to mix different constituents, in powder form, which are intended to react in a solid form in a subsequent thermal cycle. They must therefore be mixed as carefully as possible in order to limit the diffusion distances, which will result in a reduction of the calcination temperature, and avoid the formation of intermediate phases or obtain better physical properties. It is therefore essential to work with stable, deflocculated slurries before, during and after the grinding step.

Fig. 1 Influence of the viscosity of the grinding medium on the breakage of agglomerates in laminar shear layers: (a) in non-viscous media, the agglomerates are rotated by the displacement of the liquid; (b) in viscous media, a laminar flow can be established and cause the agglomerates to break up.

The fundamental aspects on the dispersion of powders in liquids and the experimental techniques allowing to characterize this state of dispersion, such as zetametry and rheology are presented below.

The Various Stages of Dispersion

The process of dispersing solid particles in a liquid can be broken down into elementary operations (Parfitt, 1981). These are in practice closely linked: the mechanical breaking of agglomerates or aggregates, the wetting, the distribution and stabilization of the slurry obtained.

Mechanical Breakage or Comminution

Mechanical grain breakage of a powdery solid refers to the disintegration or reduction of large particles which are usually aggregates (hard agglomerates: clusters of grains with strong bonds, the grains often being associated by faces) or soft agglomerates (clusters of grains with weak bonds, the grains often being associated by edges or corners). Disagglomeration can be achieved by mechanical grinding treatment. Rumpf considers three types of mechanical stress (Rumpf, 1962):

- (1) Those that can be subjected to crushed and/or sheared particles between two surfaces. In this case, the shape of the mill elements and their speed of rotation must be considered. This is for example the case of attrition grinding or laboratory grinding in a "Pulverisette Fritch".
- (2) Those associated with the impact of moving particles, either to a surface or to other particles. This is the case, for example, with impact grinding of ball mills or particles impacting against each other in a jet mill.
- (3) Those imposed by the surrounding environment: in this case, the viscosity of the dispersing medium has some influence on the comminution of agglomerates as shown in Fig. 1. It affects as well as surface strength, the penetration of the liquid into the channels of the agglomerate, which can provide sufficient pressure to disintegrate the cluster.

The nature of the dominant mechanism during a particular grinding stage or for a particular product will depend on the microstructure of the particles, i.e., the type and concentration of defects in single crystals, grain boundaries in polycrystalline materials and the nature of the bridging in agglomerates. The value of the impact fracture stress of a particle tends to increase as the particle size decreases and approaches dense single crystal materials. As a result, there is a size limit for a perfect single crystal which is, for example, in the order of 1 μm for quartz and 4 μm for calcite. Below these limit values, it is no longer possible to accumulate sufficient elastic energy in a particle, which can then only deform plastically. The attrition (shear) fracture mechanism, which is a consequence of the high stresses produced during friction between the particles, is, for sizes below these limit sizes, the mechanism for further size reduction. When the submicron range which is often desired for technical ceramics is reached, the large forces involved can deform the mesh of the crystals constituting the particles, which induces residual stresses. For a Bayer alumina, this can be a stress range of around 40 nm with dislocation densities of around 10^{11} cm^{-2} .

During grinding, very high local temperatures can be reached due to the high amount of energy released which is converted into heat at the crack propagation front or due to friction between the particles and the grinding balls during attrition. This can

Fig. 2 (a) Vector representation of the “drop model”. (b) Wetting characteristics of a solid surface.

result in a softening of the material and lead to a more plastic behavior. This heat can also result in local changes in the material, producing an amorphous layer or even a phase transformation. Mechanochemistry techniques, including the use of planetary mills with decoupled high-energy movements (pulverisette), have been widely used for metal alloys since the 1970s and in the ceramic field. (Suryanarayana, 2001; Nachbaur *et al.*, 2009).

Defects that remain in the powders after grinding can also have a positive influence on sintering by facilitating the diffusion of material components at grain boundaries or in volume. However, in all cases, the transmission of mechanical energy to the particles requires that they be thoroughly wetted beforehand in a humid environment.

Wetting

Wetting corresponds to the spreading of the dispersing liquid on the surface of the solid; it results in replacing the solid-air interface with a new solid-liquid interface. Wetting is, therefore, an interfacial phenomenon which is influenced by the thermodynamic characteristics of the interfaces of the two phases concerned (free surface energy of the solid and surface tension of the liquid). These parameters were established from the “drop model”. When a drop of liquid is deposited on a solid interface, it adopts a particular configuration that reflects the nature of the interactions between the solid and the liquid. The drop takes the form of an equilibrium that minimizes the free energy of the system.

Young proposed for this state of equilibrium the vector representation shown in Fig. 2. At point M, there is equilibrium of tensions, which is expressed by the relation:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta$$

with

γ_{SV} : Free surface energy of the solid in the presence of the vapor of the liquid; γ_{LS} : Interfacial free energy between solid and liquid; γ_{LV} : Free interfacial energy of the liquid in the presence of its vapor; θ angle of contact of the liquid on the solid, or wetting angle

The ability of the liquid to wet the solid is defined as follows:

$\theta = 0^\circ$, i.e., $\gamma_{SV} = \gamma_{LS}$, wetting is spontaneous;

$0^\circ < \theta < 90^\circ$, i.e., $\gamma_{SV} > \gamma_{LS}$, the liquid wets the solid but not perfectly (case of water on glass);

$\theta > 90^\circ$, i.e., $\gamma_{SV} < \gamma_{LS}$, the liquid does not get wet, but rather curls on the surface of the solid (case of mercury on glass).

A decrease in γ_{LS} through the use of surface active agents (dispersant or surfactant), which can adsorb to the surface, will result in a decrease of θ , therefore in increase of wetting.

The reduction of γ_{LV} can be obtained with a liquid such as ethanol whose surface tension at 20°C (23 mN m^{-1}) is about three times lower than that of water (73 mN m^{-1}).

The work required to change from a dry powder (with all surfaces exposed to the vapor phase, e.g., air) to a fully immersed powder wetted by a liquid (with only solid-liquid interfaces remaining) is described by the equation:

$$W_D = -(\gamma_{SV} - \gamma_{SL})$$

When the dispersion work is negative, then the dispersion of the powder in the liquid is a spontaneous process.

Powders of ionic materials with polar surfaces, such as oxides, can be easily dispersed in polar liquids such as water. The use of water as the main component of the dispersing liquid represents a great advantage in terms of both economic and environmental cost. Materials with more covalent bonds, such as silicon nitride or carbide, are less easily dispersed in water and the use of organic solvents is often used. Another factor to consider when selecting the liquid is the solubility of the ceramic powder in the liquid. A good wetting of the surface should not be correlated with a solubilization which would alter the composition of the powder.

Dispersion

Dispersion refers to the process by which finely divided, wetted solid particles occupy the entire dispersing medium in a very homogeneous manner. This dispersion is achieved by hydrodynamic processes. This dispersion starts with an operation involving mechanical, vibrating or ultrasonic agitation mixers. These mixers are often not enough powerful to have a disagglomeration or

Fig. 3 Model of the double layer and variation of the associated potential in the solution. Reproduced from Bockris, J.O., Devanathan, M., Müller, K., 1963. On the structure of charged interfaces. *Proc. R. Soc. Lond. A* 274 (1356), 55–79.

grinding action. However, this stage is either preparatory to the use of the slurry before attrition grinding, or after grinding to maintain good dispersion and avoid sedimentation of the powder.

Stabilization

Stabilization of a suspension means that well-divided, wetted solid particles distributed within the environment will no longer flocculate, i.e., spontaneously assemble to form clusters which could be either agglomerates or flocs (a set of agglomerates gathered into a macrostructure). Then, there is no more change over time, neither in the total number nor in the size distribution of the particles.

This step of limiting the phenomenon of flocculation or coagulation of the particles is the most important in the realization of suspensions. When dispersing very fine powders, an extremely extensive liquid-solid interface is created and a system with a high excess of free energy is formed, which is therefore thermodynamically unstable. This system tends, a priori, to evolve towards a more stable state so that flocculation must inevitably occur within any suspension.

Two physical factors are known to destabilize the suspensions:

- (1) Sedimentation. Under the effect of gravity, particles cannot remain in suspension. However, the higher the viscosity of the dispersing medium, the lower the sedimentation forces will be.
- (2) Brownian movement. Van Smoluchowski developed a theory of flocculation according to which an unstabilized suspension flocculates as a result of collisions between primary particles agitated by Brownian motion.

Physical Factors Improving Stabilization

To avoid flocculation, contact and collisions between individual particles must be limited. This can be achieved by changing the surface electrical properties of solid grains to promote electrostatic repulsion and/or by changing the minimum approach distance between the particles by adsorption of polymers on their surface, so that steric repulsion occurs.

Stabilization by Electrostatic Repulsion

This principle is based on the notions of surface charges and electrical double layer, the essential points of which are shortly reviewed below.

Fig. 4 Variations in the potential energies of attraction V_A and electrostatic repulsion V_R as a function of the separation distance between two spherical particles.

Electrical Characteristics of Powders in Aqueous Suspension

Most solid surfaces are electrically charged. On the crystal surface, not all bonds are saturated, which causes the chemisorption phenomenon. This phenomenon consists of the surface capture of foreign chemical entities (atoms or molecules) by ionic forces. The surface charge of particles dispersed in water or an electrolyte solution can become much higher than in air. This development of surface charges results either from the partial dissolution of the solid, or from the ionization of surface groups (OH^- in particular), or from the substitution of ions in the crystal lattice of the solid. These charges are compensated by charges of opposite signs (principle of electroneutrality) coming from ions in the solution (counter ions). This creates a double electrical layer, as shown in Fig. 3.

- (1) The first layer, known as the rigid (Stern) layer, is formed by contact adsorption, then by adsorbed ions with their solvation molecules. The whole is close to the solid and moves with it, hence the name rigid layer;
- (2) The second layer, known as the diffuse layer, is formed by the rest of the charges that neutralize the surface charges and are distributed within the solution.

The potential associated with this load distribution varies as also shown in Fig. 3. Its value at the OHP ("Outer Helmholtz Plane", passing through the center of the solvated ions) is assimilated to the zeta potential (ζ).

Stabilization Principle by Electrostatic Repulsion

The principle of stabilization by electrostatic repulsion has been established within the framework of the D.L.V.O. theory (named after its authors Deryagin, Landau, Verwey and Overbeek). According to this theory, the layer of adsorbed ions carries the charges and if the adsorption is uniform, all particles are charged identically. Stabilization results from the Coulombic repulsion that occurs between these particles, the value of which is directly dependent on the zeta potential. This repulsion potential is associated with the charge distribution and decreases exponentially with the distance between the particles.

The particles are also subject to the forces of attraction of London and Van Der Waals, depending in first approximation on their diameter, the nature of the material and the dispersion medium. An attraction potential V_A is associated with these forces and is inversely proportional to the distance between the particles.

As shown in Fig. 4, stabilization can only take place if the repulsion forces are greater than the attraction forces between two neighboring particles. The maximum of the resulting potential energy V_{MAX} is the energy barrier that prevents the particles from getting closer. The V_{MIN} potential represents the energy for which coagulation occurs. Flocculation would rather be the consequence of interactions that occur at approach distances and energy corresponding to a secondary minimum (Fig. 5).

Parameters That can Change the Electrostatic Repulsion Stabilization

According to the DLVO theory, under isothermal conditions and in the absence of mechanical agitation, stabilization by electrostatic repulsion depends on particle radius and their surface potential (ψ_0). Therefore, for a given suspension, the conditions of stability can be modified by changing ψ_0 . However, its value depends directly on phenomena at the origin of the surface charges like the pH of the medium, the concentration of adsorbed ions or the exchange capacity.

The diagrams in Fig. 6 show how the zeta potential and the surface charge σ_0 varies as a function of the concentration of the potential-determining ions in the medium. In particular, it can be seen that ζ and σ_0 can cancel each other out at the isoelectric

Fig. 5 Dispersion state as a function of the potential energy profile.

point (IEP) or zero charge point (ZCP), in which case V_R cancels out occurs. Conversely, the higher ζ potential, the greater the repulsive forces V_R and the more stable the suspension.

In the case of oxides in aqueous suspension, after the surface reaction which corresponds to a very strong chemisorption of the water, there are amphoteric hydroxide groups, of the M-OH type, which will be able to dissociate like weak acids or bases:

The concentrations of H^+ and OH^- ions determine the surface charge. Therefore, the pH of the suspension medium influences the stability of the suspension.

Stabilization by Steric Repulsion

Electrostatic repulsion forces alone are often insufficient to stabilize the dispersions. A main reason for this is the compression of the double layer due to too high ionic concentration. This may be due to the presence of impurities but also to the partial dissolution of ceramic powders at pH values that are in principle necessary for stabilization. These two factors become more predominant in concentrated dispersions where the solid to liquid volume ratio is high and where a low degree of dissolution can greatly increase the ionic concentration. Consequently, it is necessary to resort to other repulsion mechanisms such as those involved in the addition of soluble polymers.

Indeed, it has been observed experimentally that addition of such a polymer to a colloidal suspension can improve its stability or, on the contrary, cause its flocculation. The interpretation of these behaviors is given by the theory of stabilization by steric repulsion. The steric hindrance of the grain, surrounded by its adsorbed layer, limits the approach between particles and, therefore, at distances between particles for which Van der Waals forces predominate. This theory considers the interactions that occur when the adsorbed polymer layers on the surface of two particles come into contact (**Fig. 7**).

Another context leading to the use of polymers is that of non-aqueous dispersions, used in the case of powders that react with water, but difficult to stabilize electrostatically because of the complex charging process that prevails in these media.

Shear-Thickening Grinding Slurries

It is important that grinding slurry is characterized by a slightly shear-thickening behavior with good dispersion and low viscosity. Otherwise, a large part of the energy expended in the mill is used to deform the highly viscous fluid and to destroy the agglomerates, to the detriment of the grinding action itself.

Fig. 6 Illustration of the relationships between zeta potential, surface charges and potential variation in the double layer, in the presence of the only ions determining the potential. the charge 0 is given by the slope at the origin of $\psi(d)$, the ζ zeta potential is given by the charge values at the O.H.P.

Parameters Influencing the State of Dispersion

Certain parameters will have a direct effect on electrostatic repulsion, such as pH, steric repulsion or addition of dispersants. However, other important parameters as temperature, solid content and particle size and shape must also be taken into account.

pH

Theoretical reminders help to understand how, by tuning the pH value of the suspension medium, which directly influences the concentration of the medium in ions determining the potential; one can modulate the repulsion forces between neighboring particles. This property is known to traditional ceramists who control the flocculation or deflocculation of clay slurries by playing on the pH value generally by basic additions. In this case of traditional ceramics, the rheology is complicated, which is a consequence of the anisotropic shape of the particles as well as the inhomogeneous distribution of the fillers. At pH values below about 8, kaolinite platelets carry negative charges on the developed surfaces and positive charges on the tips and edges. This leads to a microstructure like a house of cards which, in the case of high volume fractions, leads to a continuous network and the existence of a flow threshold. At higher pH values, all surfaces become negative and a minimum of the viscosity value is observed (Fig. 8). As the particle size decreases, both the flow threshold and the minimum viscosity increase due to the higher number of contacts per unit volume, although the force per pair of interactions decreases.

Other examples of the evolution of the viscosity of suspensions as a function of pH and consequently of the zeta potential will be studied in experimental applications described below, with their associated rheological behavior.

To adjust the pH of the slurries all types of acids or bases can be used. In the traditional ceramic industry are used: sodium silicate, bicarbonate, metaphosphate, triphosphate, soda, potash, etc. They are called inorganic dispersants; in addition to adjusting the pH, they increase the ionic strength of the medium by adding sodium or potassium cations. In the preparation of technical ceramics, acids or bases that can bring undesirable ions are excluded. This limits the range of products that can be used. Diluted ammonia solutions can be used to adjust basic pH values and for acid pH values hydrochloric or citric acids.

Fig. 7 Diagram illustrating the steric prevention of contact between two solid particles thanks to the layer of polymer adsorbed on the periphery of the particles.

Fig. 8 Viscosity variation of kaolin and ball clay suspensions as a function of pH and schematic representation of the microstructure of the suspension.

Solid Content

It is also understandable that the slurry behavior also depends on its dry matter concentration (the solid content, often expressed as a mass or volume % of dry powder in the slurry): the final electrical equilibrium of the suspension and the pH of the slurry depend, among others, on the total surface area of the powder grains likely to react with the dispersing medium. In general, as any other parameter is constant, increasing the solid load will change the rheological behavior: for example suspensions with low concentrations of oxide in water will maintain Newtonian behavior and this behavior will become shearthinning by increase of the solid load with increase in viscosity values as shown in [Fig. 9\(a\)](#).

Temperature

Temperature is a parameter to be considered, especially in high energy mills where the slurries temperature can exceed 60°C. Generally speaking, the increase in temperature favors the Brownian movement and reduces the viscosity of the slurries and the flow threshold, as shown in [Fig. 9\(b\)](#).

Fig. 9 Effect of (a) the solid load (Φ being the volume charge) and (b) the temperature on the rheological behavior of aqueous TiO_2 slurries according to Yang *et al.* Reproduced from Yang, H.-G., Li, C.-Z., Gu, H.-C., Fang, T.-N., 2001. Rheological behavior of titanium dioxide suspensions. *Journal of Colloid and Interface Science* 236, 96–103.

Dispersants

Although the term dispersant is also used for pH-adjusting inorganic compounds, we will only refer here to organic dispersants, which are also called deflocculants or surfactants. They provide steric stabilization and also have a pH-adjusting role.

The types of polymers used are very varied. They include polyelectrolytes, used in the case of aqueous or polar media; non-ionic polymers, mainly used for low-polar media; copolymers (random or block) which have one (or more) adsorbant entities and one (or more) entities which are not adsorbed and tend towards solution.

The Fig. 10 shows the main water-soluble polymeric dispersants used in the ceramic industry. There are also a large number of dispersants sold by suppliers under trade names and it is often difficult to know their precise formulation.

A typical example of an ionic surfactant with a hydrophilic head and a hydrophobic tail is sodium dodecyl sulfonate (DSS) shown Fig. 11. The chemical nature of the powder (hydrophilic or hydrophobic) and the dispersive liquid can greatly influence its wettability and the dispersion of the powder.

Random copolymers have non-ordered side chains like a bottle brush and block copolymers have ordered side chains like a toothbrush. Stabilization by these polymers obviously requires their adsorption as an essential first step. This is due to the respective affinities of the solvent and the polymer for the surface of the ceramic powder or, in other words, the adsorption energy required to develop sufficient adhesion of the polymer to the surface. This can have implications for the shaping process as the polymer can then be subjected to high shear rates. Desorption of the polymer would reduce the degree of overlap with the result that the particles would be brought closer together or bridged by the polymers still present. In both cases, strong attractive forces develop and can strongly modify the rheological behavior. It should therefore be noted that in order to achieve good repulsion, the surface must first of all be well covered by the polymer and then this covering must remain constant during the approach of the particles (which is tantamount to expressing that the time scale of desorption is much greater than that of adsorption).

The polymer must also have a certain affinity for the solvent. This is necessary so that it can spread sufficiently towards the solution to develop good steric repellency. Indeed, it is at the moment when the covering of the adsorption layers begins that the repulsion is felt. The more these layers are extended, the more the approach and therefore the effect of the Van der Waals forces will be limited. When the layers overlap, there is interpenetration of the polymers and the contact between the solvent and the polymer chains is reduced (due to polymer-polymer contact). As a result of the adsorbed layer approach, each polymer can no longer adopt as many configurations as before. The density and configuration of the adsorbed polymers play therefore a critical role in dispersion stabilization.

Adsorption conformation plays a key role in steric stabilization. For example, the different modes of adsorption used to describe the adsorption at different pH values of polyacrylic acid (PAA) on an alumina surface are schematically depicted in Fig. 12. (Pederson and Bergström, 1999).

At low pH values, PAA is not dissociated and is only adsorbed with few points of contact on the surface. The volume it occupies in such a way is close to that which it occupies when in solution. In this case we speak of a random ball configuration (Fig. 12(a)). At higher pH but still below the isoelectric point of alumina (e.g., pH 6), the PAA is completely dissociated into a negatively charged polyelectrolyte which will be adsorbed onto the positively charged alumina in a horizontal configuration. This is known

Fig. 10 Main water-soluble polymeric dispersants.

Fig. 11 An ionic surfactant: sodium dodecyl sulfonate (DSS) and its schematic representation.

Fig. 12 Schematic representation of the adsorption of PAA on an alumina surface at different pH values showing some possible configurations: (a) random coil, (b) flattened (pancake), (c) loop (mushroom), (d) brush.

as flat or pancake adsorption (Fig. 12(b)). At even higher pH values, close to but below the isoelectric point (e.g., pH 8), the electrostatic interaction energy between the polymer and the surface decreases and the adsorption mode is described more in terms of loops and segments (Fig. 12(c)). It can also be qualified by the term *fungus* in some cases. This term suggests that the density of polymer segments is higher in the middle of the adsorbed layer than at the surface of the solid. When pH is above the isoelectric point, the surface has very few positively charged adsorption points. Most of the surface exhibits electrostatic repulsion with the

Fig. 13 Grains undergoing attrition shear between grinding balls.

polymer. As a result, the polymers will only be adsorbed at a few points and will repel each other, limiting the degree of coverage. In this case, the adsorption mode is said to be in a “brush” type configuration (**Fig. 12(d)**). It has to be noticed that between these different situations, the conformation of the polymer in solution is no longer the same, the volume of the macromolecules evolves with their dissociation rate and the thickness of the adsorption layer is therefore modified. The charge associated with the polyelectrolytes will also influence the electrostatic forces. When there are both electrostatic and steric forces, the term electrostatic repulsion is generally used.

The advantage of co-block polymers is that they can combine high adsorption while maintaining a large and better defined adsorption layer thickness than in the case of a PAA type polymer with a very large molecular weight polydispersity. Unfortunately, these polymer co-blocks are very expensive and not commercially available. For this reason, high polydispersity PAA with poorly defined and highly variable adsorption layers are still widely used and their dispersion efficiency is difficult to predict. It should be noted that an inexpensive intermediate solution is the use of polyacrylates with PEO side chains that define the thickness of the adsorption layer. These materials are already widely used in the cement industry.

The addition of organic dispersant is necessary when simple electrostatic repulsion is insufficient, or even impossible in the case of powder mixtures that have opposite evolutions of their zeta potential according to the pH. It will then allow the viscosity values of the slurries and the flow thresholds to be lowered and the rheological behavior to be completely changed from shear-thinning to -thickening when the slurry is completely deflocculated. This is for example the case of mixtures of TiO_2 and MgO in water which will be detailed below.

Grinding

When grinding slurries, if it is efficient, there will be an increase in the surface area developed by the powder. The new surface created will react with the dispersing medium. This will result in a modification of the pH of the slurry and/or a change of the surface concentration of adsorbed dispersants. In addition, there will be a decrease in the diameter of the powder grains, resulting in evolution of the Van der Waals forces. Thus, very large changes in slurry rheological behavior are to be expected during grinding. Therefore, even if efforts have been made to obtain low viscosity and a slightly rheo-thickening rheological behavior of well deflocculated slurry for the grinding process, then it is highly likely that this behavior will change with re-flocculation of the slurry. This can then be damaging to the grinder, which may even block. Such an example will be described in a case study at the end of this chapter. A preliminary study is therefore often necessary before implementing powder treatment in a mill. Indeed, the modes of action of the various grinding devices are quite different as described below.

The Different Shredders

Grinding reduces particles down to a few tens of microns or even less. Fine grinding produces submicron particles, typically with a diameter between 1 and 0.1 μm . Fine grinding is generally associated with a greater input of energy through vibration, shear (attrition mills) or high speeds (impact mills). Such high energies allow finer products to be obtained and submicronic particles can be obtained as long as the grinding bodies are judiciously chosen to limit contamination.

Attrition Mill

In the attrition mill, the incoming material has generally a diameter of less than 50 μm . The high turbulence due to agitation results in stresses being applied to the large particles in compression and shear, as well as high collision frequencies which lead to

Fig. 14 (a) Vertical laboratory grinder, (b) horizontal grinder Dyno-mill ©.

rapid grinding kinetics. High stress is induced when the particles friction between the balls. This results in the predominant phenomenon of shear attrition. Attrition arises in addition to compressive stresses resulting from direct collisions. The diagram of [Fig. 13](#) clearly shows that there must be a match between the diameter of balls and the diameter of grains to be ground: if the ratio between the two diameters is too large, the limit angle determined by the value of the friction coefficient is exceeded and the grain is pushed and no longer ground between adjacent balls. This is why attrition is only used for powders that are already micron-sized.

Typical attrition mill or grinders are presented in [Fig. 14](#). Balls are agitated by blades or arms. The viscosities of the slurries, as well as the dispersion state of the particles are critical factors in such mills. These types of mills can be used in continuous mode ([Fig. 14\(b\)](#)), by pumping the slurry through the grinding volume, with the balls being retained by a suitable screen. Slurries can be recycled if a single pass does not produce the desired grain size distribution and a classification step can be added to remove the finest particles that no longer change size but occupy unnecessary volume in the grinding chamber. The solids content of a suspension is normally between 30% and 70% by mass, depending on the viscosity of the liquid phase and the size of the incoming product. The grinding balls used in attrition mills are very hard (mostly yttria-doped zirconia) and well calibrated. Ball diameters range from 2 to 0.1 mm. It will be shown later that the diameter of grinding balls has a great influence on the grinding efficiency.

Planetary Mills

The planetary shredder owes its name to the planetary movement of the bowls. In this type of mill, the bowls containing the grinding balls are held on a main disc ([Figs. 15 and 16](#)). There is a double rotation movement: the rotation of the bowls on their own axis and the rotation of the main disc around its axis.

In order to achieve efficient shredding, it has been shown by computer simulation that the main disc and bowls must rotate in opposite directions. This means that the centrifugal forces act in opposite directions. As a result, the balls roll along the inner walls and grind the powder grains between the balls and the wall leading to friction effect. Under the effect of centrifugal force, the balls are then violently ejected onto the opposite wall and thus impact the powder grains ([Fig. 15\(b\)](#)).

The grinding bowls have a capacity of 12–500 mL and the balls have diameters of 5–40 mm. As the bowls are closed and sealed, some equipments allow working under controlled atmosphere. The choice of the material for bowl and balls is very important because when the balls impact onto inner wall, particles from the bowl can be ejected and therefore incorporated into the powder. This can lead to contamination and thus modify the desired composition. It is therefore essential to choose a very hard material in order to resist abrasion. Materials available are agate, corundum, silicon nitride, zirconium oxide, steels. Balls with

Fig. 15 (a) Principle of the planetary mill with the rotation axes of the bowls and the disc, (b) balls trajectory.

Fig. 16 (a) Pulverisette P4 Fritsch, (b) grinding bowls.

high densities are preferred because their kinetic energies are higher. The literature shows that using balls of different sizes within the same bowl is not a satisfactory solution because the trajectories of the balls are modified which prevents the homogenization of the sample.

The effectiveness of a mechanical shock depends on the density of the ball and its speed. Thus it depends on the rotation speed of the disc and bowl. As a first approximation, it is easy to estimate that the higher the speed of rotation, the higher the speed of the balls and that, consequently, the more efficient the grinding would be. This is true up to a so-called critical speed. Indeed, if the rotational speeds are too high, the centrifugal force due to the support disc is not large enough to compensate for the centrifugal force due to the rotation of the jar. This causes the balls to roll on the inner wall without ever hitting the opposite wall. This only results in friction effects, resulting in inefficient grinding. This is why it is necessary to use speeds below the critical speed but high enough to ensure efficient grinding. There is no referenced speed because it depends on the composition of the powders, the size of the balls, the nature of the balls and of the bowls. Most planetary mills have a fixed speed ratio. The speed ratio is the quotient of the bowl speed over the disc speed. Only the Fritsch planetary mill, Pulverisette 4 (Fig. 16), allows to select a ratio. Grinding can be carried out in a dry or slurry process. In both cases, the bowls should be filled to about 50% by volume. This way the balls have enough space to acquire their maximum speed. If the bowl is filled with powder and beads then the beads have a very low speed and the energy on impact with the powder is very low. On the other hand, if there are very few balls and powder in the bowl, the efficiency is very poor.

Another variable to take into account is the BPR, an acronym of Ball to Powder weight Ratio. It corresponds to the quotient of the mass of balls on the mass of powder. For example, a BPR of 10:1 means that the mass of balls in the bowl is ten times greater than the mass of powder. At high BPR values, there are a large number of balls and therefore a large number of collisions per unit of time, resulting in more efficient and faster grinding. If there is very little powder, the majority of collisions will be useless for grinding. This is why, in accordance with studies that have varied the BPR from 1:1 to 300:1, it is advisable to use a BPR of between 5:1 and 20:1.

Fig. 17 Diffractogram after drying of an “MgO”/TiO₂ mixture carried out in an aqueous medium.

Examples of Application

Several papers undergoing optimization of grinding process have been published, for example grinding of TiO₂ and Al₂O₃ (Houivet and Haussonne, 2003). Two examples showing the importance of grinding and milling for electronics applications are described below. The first one will be for multilayers ceramics capacitors used for medical application and the second for use as sensor in automobile.

First Example: Synthesis of MgTiO₃ for Multilayer Capacitors Type I

The difficulty of obtaining pure MgTiO₃ ilmenite phase is frequently reported in the literature. Indeed, the synthesis of MgTiO₃ is commonly accompanied by non desirable formation of MgTi₂O₅. In industrial production, as the reproducibility of batches is crucial to obtain satisfactory type I multilayer capacitors. (Bernard *et al.*, 2008), some specific processes have been developed.

Stabilization tests by electrostatic repulsion of MgO/TiO₂ slurry

In principle, synthesis can start from pure magnesium oxide (MgO) and titania (TiO₂). As magnesium oxide has a strong tendency to form hydrate and carbonate, it should practically be calcined before handling (e.g., 2 h, 600°C). However, for economic reasons, mixing has to be carried out in aqueous medium. In these conditions MgO forms Mg(OH)₂ (brucite), while TiO₂ (anatase) retains its structural characteristics. The diffractogram (after drying) of the obtained mixture of MgO and TiO₂ after processing in aqueous medium (50% mass in solid) is shown in Fig. 17. It confirms that all the MgO is hydrated into brucite.

The zetameter analysis of this mixture is given in Fig. 18. The zeta potential values of titanium oxide as a function of pH are in accordance with a classical evolution with pH. Indeed, the potential is highly negative (< -30 mV) for basic pH values whereas it becomes positive in acidic environment. The isoelectric point is close to pH 3. The behavior of magnesium oxide is different: zeta potential of brucite remains close to 0 over the pH range 12 to 8.5 and values at pH below 8.5 cannot be determined, as Mg(OH)₂ dissolves quickly under pH 8. Therefore, it can be concluded that it is not possible to obtain a stable aqueous dispersion of a mixture of MgO and TiO₂ powders in the pH range between 8.5 and 12. Furthermore, as dissolution of magnesium hydroxide occurs at pH < 8, it is thus difficult to mix at low pH values. Moreover, low pH conditions are not favorable because the zeta potential of titanium oxide at slightly acidic pH is low. This simple zetametric study shows clearly the impossibility to obtain favorable mixing conditions for aqueous slurries starting from MgO and TiO₂ by controlling only on electrostatic repulsion.

To confirm this issue, the rheological record (Fig. 19), of MgO (Mg(OH)₂)/TiO₂ slurries in stoichiometric proportion confirms their flocculated character. In fact, in a more concentrated medium (as a slurry), magnesium oxide imposes the pH of the slurry (natural pH after mixing is 11.3). Even if the solid content is reduced (i.e., 25% mass), there is no stabilization regardless the pH values. Recording the rheogram at this low concentration and pH also shows a shearthinning behavior of the slurry, confirming the

Fig. 18 Variation of the Zeta potentials of brucite and anatase as a function of pH.

Fig. 19 Rheogram of a MgO/TiO₂ slip in an aqueous medium at 25% solid load.

flocculated character of the suspension. As a consequence, another solution has to be used: steric repulsion technique as described below.

Steric repulsion stabilization

Addition of a dispersant makes it possible to obtain deflocculated slurries by influencing the distances between particles. In this example, the dispersant chosen is Dolapix CA[®], a basic anionic polyelectrolyte.

Experimental slurries consist of a stoichiometric mixture of MgO/TiO₂. The rheograms assembled in Fig. 20 show the rheological behavior with increasing contents of Dolapix CA on 80 cm³ of slurry (25% solid mass). Addition of only 1 cm³ (i.e., 1.25% by volume) of dispersant allows to reduce the viscosity by a factor of 30 at low velocity gradients. The change from shear-thinning to shear-thickening behavior takes place, as soon as 2 cm³ of dispersant is added to the 80 cm³ of slurry. The rheo-thickening character is totally obtained for an addition of 2.5 cm³. The same shear-thickening behavior can be obtained with more concentrated slurry: 50% mass (Fig. 21). Despite a higher solid load, the volume of dispersant required to obtain 50% mass deflocculated slurries is less than that of 25% mass deflocculated slurries. This observation may seem paradoxical. The envisaged hypothesis is that there is a different grafting rate of the solid particles on the polymeric dispersant between diluted (25%) and concentrated (50%) media. Indeed, in diluted media, the distances between particles/particles and particles/dispersant are larger than in concentrated slurries. It signifies that, for 25% slurries, the particles have less probability to come into contact with the polymeric dispersant, the grafting rate of solid particles on the polymer chains is thus lower than for 50% slurries. This is equivalent to assuming that in diluted medium, the dispersing chains would remain free with a different ratio of free chains to chains grafted between 25% and 50% of suspensions. This also implies the existence of an optimum where the solid load would

Fig. 20 Evolution of the viscosity of a MgO/TiO₂ slurry at 25% solid load as a function of the volume of dispersant added.

Fig. 21 Evolution of the viscosity of a 50% MgO/TiO₂ slurry in solid load as a function of the volume of dispersant added.

be maximum and the amount of dispersant to obtain shear-thickening behavior would be minimum. Tests on 66.6% solid suspensions carried out show that it is not possible to obtain deflocculated suspensions, whatever the amount of dispersant added. However, in the case of suspensions deflocculated at 50%, it should be noted that, despite the shear thickening behavior obtained, the viscosity is increased by a factor of 2 compared to the viscosity of the suspensions deflocculated at 25%. As it is possible to obtain optimum mixing/grinding conditions for the MgO/TiO₂ slurry, the influence of the mixing conditions on the formation of the ilmenite MgTiO₃ phase is studied (see below).

Influence of rheology on the synthesis of MgTiO₃

Attrition grinding tests are also carried out starting from 2 different rheological slurry behaviors: rheo-thickening and shear-thinning. The last were obtained from slurries of 50% solid load, 1 to 1 MgO/TiO₂ stoichiometry, stirring in aqueous medium. The attrition time is set at 60 min. To obtain deflocculated slurries, all the conditions defined above are followed: addition of Dolapix CA (1 and 2 cm³) to optimize dispersion. The various slurries are then spray dried to avoid any sedimentation phenomena and then calcined during the same thermal cycle including a 1000°C, 1 h dwell. After chamottage, the powders from both mixtures (flocculated and deflocculated) are analysed by X-ray diffraction. **Fig. 22(a)** shows that pure ilmenite phase is observed in the case of a mixture with perfectly controlled shear-thickening behavior. On the contrary, starting with uncontrolled viscosity (shear-thinning behavior), traces of MgTi₂O₅ phase are detected in X-ray diffraction (**Fig. 22(b)**). It shows the importance of controlling the rheology during mixing/grinding to obtain pure magnesium titanate. This can be explained because under optimized deflocculation conditions, oxide grains are more homogeneously distributed. As a consequence, diffusion distances during chamottage are lower favoring synthesis of the pure phase.

Second Example: Negative Temperature Coefficient Ceramics – Synthesis of the NTC Ceramic $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$

The compositions belong to the Y_2O_3 - Cr_2O_3 - Mn_2O_3 system in order to produce ceramic thermistors with negative temperature coefficient (NTC) that can be used in temperature ranges from ambient to 1000°C . These compositions are often very difficult to densify because sintering temperatures are higher than 1600°C . Through the development presented below, it is intended to show how a control of mixing and grinding allows improving densification, in this example of the $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$ phase.

Mixing conditions of the oxides

The precursors are Y_2O_3 , Cr_2O_3 and Mn_2O_3 , mixed in stoichiometric proportions to obtain $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$. **Fig. 23** represents their zeta potential as a function of pH. The 3 oxides exhibit zeta potentials larger than 30 mV (in absolute value) for pH between 10 and 12. This pH range is thus favorable for dispersion. The slurries rheological behavior is shown in **Fig. 24** (40% solid mass, water): a comparison is made between mixture at natural pH (6.6) and the same for pH increased at 10.6 by ammonia addition. On the one hand, at pH 6.6, the rheological behavior is typical of the shear-thinning type at low velocity gradients, which corresponds to a flocculated mixture. On the other hand, at basic pH, the behavior of the mixture is slightly rheofluidifying, i.e., the mixture is deflocculated, in good accordance with the zeta potential results. The perovskite $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$ phase can be obtained almost pure after calcination above 1150°C as shown by X-ray diffractograms, **Fig. 25**. However, during the formation of the phase, there is a volume increase, shown in the dilatometric curves of **Fig. 26**. This leads to cracking of the ceramics during reactive sintering. To avoid such a phenomenon, mixing and grinding of raw materials and regrounding of $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$ calcinated powders has to be performed.

Influence of raw material grinding times on $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$ calcinated powders

Mixtures of the 3 raw powders are ground in a Dyno-mill[®] device, using 0.8 mm yttria zirconia balls (40% solid mass, pH = 11). During the grinding of a 500 g batch of powder mixture, slurry samples are taken after 15, 30 and 45 min. The samples are dried then calcined at 1200°C for 1 h. The calcined powders are then roughly deagglomerated with mortar.

Characterization of calcined sample powders by laser granulometry (**Fig. 27**) and by specific surface area measurement (**Fig. 28**) show that calcination leads to aggregation. Indeed, the average size of the agglomerates measured by Laser granulometry is around 5 μm , whereas the estimate of individual grains by BET would be rather around 0.5 μm for calcined powders resulting from a 45 min powder grinding. This is confirmed by SEM (**Fig. 29**). We are dealing with very porous aggregates, formed by grouping grains that have undergone a beginning of sintering as confirmed by the formation of necks between grains. Such aggregates should lead to a heterogeneous powder compact, which can lead to differential sintering and thus to the development of large pores and cracks in sintered materials. As a consequence, it is necessary to reground these calcined powders before sintering.

Grinding of calcinated $\text{YCr}_{0.5}\text{Mn}_{0.5}\text{O}_3$

A 500 g batch of A3 pre-calcined powder (45 min) is reground in the same conditions as before. Samples are taken again during grinding (B1-15, B2-30 and B3-45 min). The grain size distributions of the 3 calcined powders issued from regrounding

Fig. 26 Dilatometric curves of mixtures ground with Dyno-mill[®] and laboratory attritor for 30 min.

Fig. 27 Granulometric distribution of calcined powders A1, A2 and A3.

(Dyno-mill[®]) are shown in Fig. 30. Unsurprisingly, the particle size decreases with increasing regrind time. Indeed the median diameter of A3 (unground calcined powder) decreases from 4.5 μm down to between 1 and 2 μm , depending on the re-grinding time. The evolution is more evident with regard to the specific surface (Fig. 31): surface area increases from 2.1 for A3 mixture to 7.2 m^2/g for a regrinding time of 45 min. This corresponds to 0.5 and 0.1 μm BET equivalent diameter, respectively. It has to be noted that during grinding, wear of zirconia balls can occur. Indeed by weighting balls before and after twice 45 min grinding, zirconia total mass has diminished of 0.4%.

Effects of grinding on densification

Dilatometric analyses carried out under oxygen flow up to 1600°C reveal that the shrinkage start is around 1300°C for all unground calcined powders. For reground calcined powders (B series), there is a slight temperature shift at the beginning of the densification and an increase in shrinkage, which suggests that the ceramic will be denser over the grinding time, as green densities are similar (Fig. 32). It should be noted, however, that despite this slight improvement in sinterability, the shape of the curves suggests that none of these samples are fully densified during these dilatometric measurements. To increase the final density, sintering can be performed in a kiln at the same temperature (1600°C), under oxygen flow, with a dwell time of 12 h. From the densities represented in Fig. 33, it can be seen the significant effect of grinding on the densification level as the density increases up to 95%.

Fig. 34 Diffractograms of sintered ceramics compared to calcined powder.

Characterization of ceramics made from reground calcined powders

The diffractograms of the sintered ceramics are collected in **Fig. 34**. Two phases are present: the expected perovskite phase $Y(Cr,Mn)O_3$ which is a solid solution where Mn is substituted for Cr and which remains isomorphic to the $YCrO_3$ phase listed in JCPDF 0034-00365 and a secondary phase identified as an yttrium oxide Y_2O_3 phase. (Tachiwaki *et al.*, 2001) also observed this second phase by synthesizing $YCr_{1-x}Mg_xO_3$. In the synthesis of $Y_{0.8}Sr_{0.2}MnO_3$ and $Y_{0.9}Sr_{0.1}MnO_3$ (Agüero *et al.*, 2002) yttrium oxide is also encountered as a secondary phase. This secondary phase could be stabilized by the ZrO_2 pollution resulting from the wear of the balls. The SEM microstructures (**Fig. 35**) confirm the densification levels. EDS shows also that gray zones can be attributed to perovskites, whereas small light gray spots are richer in yttrium and would correspond to yttrium oxide, in accordance with XRD data.

Fig. 36 Representations $\ln(\rho) = f(1/T)$ from 25 to 1000°C.

Materials for temperature sensors are mainly characterized by two electrical parameters: the resistivity (ρ) at 25°C and the energy constant (or “B” parameter) which is minus the slope of the linearization $\ln \rho = f(1/T)$. The Fig. 36 shows the variation of $\ln \rho$ as a function of $1/T$ up to 1000°C. As expected, a decrease in resistivity is observed with increasing temperature.

However, $\ln \rho$ is not linear with the inverse of temperature over the entire temperature range: an inflection in the 600–700°C zone is observed leading to identify two linear domains (noted I and II, respectively) which must represent two conduction phenomena activated in different temperature ranges. In their work on substituted YCrO_3 and LaCrO_3 , (Weber *et al.*, 1987) pointed out that the linear dependence of $\ln(\sigma T) = f(1/T)$ is characteristic of a small polaron transport mechanism between cations of the same element on the same crystallographic site, but of different valence (or hopping). In the study of electrical properties of $\text{La}_{1-x}\text{Ca}_x\text{Cr}_{1-y}\text{Ca}_y\text{O}_3$ between 400 and 1100°C, (Sakai *et al.*, 1990) found a similar dependence and claimed that this type of conduction is often a characteristic of chromium-based perovskites. With regard to the effect of grinding on resistivity, a decrease in resistivity appears as a function of grinding time with resistivity values of the same order of magnitude ($10^4 \Omega \text{ cm}$).

The energy constant of the material (B) is calculated for both temperature ranges. In range I, the constant B was evaluated between 25 and 100°C. B varies between 3600 and 3850K. It can also be seen that the energy constant decreases as the grinding time of the initial mixture increases. In range II, B was evaluated between 700 and 800°C. B values are higher reaching around 10,000K. These two decreases in resistivity and parameter B with grinding time have to be correlated on the one hand with the densification increase and with the ball contamination increase leading to the appearance of the secondary phase Y_2O_3 .

Summary

This chapter presents the main theoretical considerations concerning dispersion of mineral powders in slurries and some examples showing the strong impact of the mixing and grinding steps on the properties of ceramics for electronic: dielectric compositions for capacitors and NTC ceramics.

The importance of a perfect dispersion of the powder before grinding is highlighted in order to eliminate flocculates and agglomerates. It makes it possible to obtain sufficiently fluid slurry to undertake the grinding step with good efficiency. Rheology has proven to be an extremely effective tool for controlling slurry. Then, during the grinding process, care must also be considered to keep constant slurry dispersion conditions (by controlling viscosity and adjusting pH and/or adding dispersant) in order to maintain good grinding efficiency. By this way, reagglomeration can be avoided when shear stresses decrease, for instance at the exit of the continuous mill or when the mill is stopped or simply to avoid strong agglomeration during grinding (settling). It is then possible to obtain very homogeneous powder mixtures with fine grains (down to nanometric size) which will be more reactive and will lead to the formation of pure phase generally difficult to get by another way. These optimized powder mixtures will have a better sinterability and will develop highly controlled microstructures, particularly in the context of subsequent rapid sintering (flash, SPS or microwave sintering). The prospects of this approach considering the control of the dispersion conditions combined with grinding with high energy mills are limitless as it is applicable to all ceramic compositions. In fact, too many research works are still using recipe that is difficult to transpose to the industrial environment where powders are mixed for extremely long periods of time.

Powder Granulation and Compaction

Ceramic components are manufactured starting from inorganic raw materials in powder form. Ceramic powders are typically granulated to improve powder handling and processability, especially when dry or semi-dry powder pressing (i.e., < 8 wt% water) is performed (Lukasiewicz and Reed 1978; Reed, 1995; Ewsuk, 2001; Oberacker 2012). Dry pressing is the preferred technology for high-volume manufacturing of relatively simple geometry powder compacts, because economical and versatile. The aim is to turn loose powders into a green compact with desired shape and maximum bulk density. In addition, minimal density gradients and close geometrical tolerances are required to green compacts. The shaping pressure (usually between 15 and 200 MPa) should be high enough to produce a homogeneous green compact with enough strength for subsequent handling/debinding/sintering, but low enough to avoid excessive wear on the press and die).

Powder Granulation

Free flowing powders are used in dry pressing to uniformly fill the die, and to form a compact with homogeneous microstructure and suitable strength. Since the particles of ceramic bodies exhibit poor flow and compaction behavior in their raw form, they must be granulated. Granulation is the process of intentionally agglomerating fine particles into larger particle clusters that exhibit improved handling and flow characteristics (Ewsuk, 2001). Spray drying typically produces subspherical granules with diameter in the 100–800 μm range and mode of 100–300 μm , starting with 0.5–10 μm median particle size powders (Lukasiewicz, 1989; Soldati *et al.*, 2018a).

Granulation

Granulated powder for pressing is generally produced by either spray granulation or spray drying (Lukasiewicz, 1989; Reed, 1995; Raghupathy and Binner, 2011; Oberacker, 2012; Vicent *et al.*, 2012). Spray granulation can be performed by different techniques (Fig. 1). Both processes tend to form equiaxial granules. Relative to spray drying, spray granulation generally produces a granule morphology having a more irregular shape, and granules of higher density. Spray drying produces spherical granules with internal cavity in case of deflocculated slurry (Walker and Reed, 1999).

Spray drying is the most common technology of granulating ceramic powders for dry pressing. It involves pumping slurry to an atomizer, where small spherical droplets are sprayed into a large chamber. Heated air flowing in the chamber dries the droplets to form granules that are collected at the base of the drier (Lukasiewicz, 1989; Bertrand *et al.*, 2005). Different layouts of spray driers can be used, according to productivity, slurry characteristics, and agglomerate size.

Spray granulation consists in spraying water on powders and promote agglomeration in rounded shapes by tumbling. Excess of water can be successively removed by partial drying (e.g., in fluid bed drier). A seed is progressively enveloped in several layers of primary particles. Techniques employed in ceramic production include: vertical axis turbine, intensive mixer, press agglomeration, and sinusoidal granulator (Fig. 1).

Another alternative to spray drying is freeze granulation, which consists in rapid freeze of slurry droplets in liquid nitrogen before being recovered and subsequently freeze-dried (Vicent *et al.*, 2012).

Characteristics of Granules

The main properties of granules are: agglomerate size and shape distribution, distribution of moisture or additives as a function of size, powder rheology, and mechanical properties (yield strength). A range of rheological properties of powders are usually determined (Santomaso *et al.*, 2003; Geldart *et al.*, 2006; Nebelung and Lung, 2009; Soldati *et al.*, 2018a) by methods resumed in Fig. 2.

The characteristics of spray-dried granules are largely influenced by the physical properties of the slurry that is sprayed into the heated chamber (Lukasiewicz, 1989; Walker *et al.*, 2000) and by processing parameters (temperature, slurry pressure, number, and type of nozzles, etc.). Properties can be controlled to get spherical granules that can pack more efficiently, and lower density granules with lower strength that can deform more readily during pressing. Flocculated and deflocculated slurries produce agglomerates, respectively, without or with an internal cavity (Walker and Reed, 1999; Bertrand *et al.*, 2005).

To ensure good packing density, free-flowing granulated powders are required to ensure packing uniformity, and reproducibility in die filling. Ideally, powders with satisfactory fluency are subspherical or equiaxial, and have a size distribution between 200 and 600 μm . However, the granule size distribution is not crucial for powder fluency, unless the orifice light is less than approximately 10 times the granule diameter.

Typically, powder flow rate is determined as the time it takes a given mass of powder to flow through a certain funnel. Powder flow also can be assessed by the angle of repose that a loose powder makes when poured onto a flat surface (static) or the average angle during powder tumbling in a rotating cylinder (dynamic). Granulated ceramic powders with good flow generally have a static angle of repose of 35° or less and a dynamic angle of repose between 40° and 45° (Geldart *et al.*, 2006; Soldati *et al.*, 2018a).

Fig. 1 Granulation techniques used to produce agglomerated ceramic powders.

Fig. 2 Methods used to determine the rheological properties of ceramic granulates.

Poured density is a measure of the weight-to-volume ratio of a loose powder filling a given container. Tap density is the same weight-to-volume ratio after tapping with a prescribed procedure. The Hausner ratio, i.e., the ratio of the tap to the poured density, is also a measure of flow commonly used in ceramic manufacturing. Better powder flow and die fill reproducibility are achieved with a Hausner ratio below 1.2 (Santomaso *et al.*, 2003; Soldati *et al.*, 2018a).

Organic Additives

Organic additives are commonly added to a ceramic powder as processing aids. Addition can be done immediately prior to, during, or immediately following granulation. Table 1 lists some typical organic additives used in ceramic powder pressing including binders, plasticizers, and lubricants (Reed, 1995; Ewsuk, 2001).

Table 1 Organic additives commonly used in ceramic powder granulation and compaction

<i>Binders</i>	<i>Plasticizers</i>	<i>Lubricants</i>
Acrylic resins	Ethylene glycol	Aluminum stearate
Acrylic ± wax emulsions	Glycerol	Magnesium stearate
Methyl cellulose	Polyethylene glycol	Oleic acid
Polyvinyl alcohol (PVA)	Triethylene glycol	Paraffin wax
Polyethylene glycol (PEG)	Water	Stearic acid
Waxes and wax emulsions

Organic binders, e.g., polyvinyl alcohol, are utilized to enhance processability and to provide strength to the pressed powder compact for subsequent handling and/or machining (Lukasiewicz, 1989; Reed, 1995). The organic binders form bridges between the particles in a granule in order to improve its strength and deformation under pressure (Ewsuk, 2001; Carneim and Messing, 2001).

Plasticizers are organic molecules that can modify the structure built by binders, systematically disrupting bridges and making them more flexible by lowering their glass transition temperature (Balasubramanian *et al.*, 2002a). Combination of plasticizers with binders allows to produce granules with improved compaction through a more deformable behavior.

Lubricants are low molecular weight organic molecules that lower interfacial frictional forces between individual particles, and between particles and die surfaces. Once added to powders, they are able to mitigate friction effects during processing, thus improving powder compaction, and to reduce the pressure required for compact ejection (Balasubramanian *et al.*, 2002b). Also, solid lubricants can be utilized, as graphite (Ravindran *et al.*, 2013).

Compaction Techniques

Granulated ceramic powders are compacted by either isostatic or uniaxial pressing or by calendaring. Mechanical, hydraulic, or direct electrically driven presses are used in ceramic manufacturing.

Typical capacity of eccentric mechanical presses is in the 0.1–8 MN range, while cam-driven mechanical presses have capacity of about 1 MN. Standard hydraulic presses exhibit a wider power range, between 0.1 and 160 MN. The direct electrically driven press may reach pressures up to 0.2 MN. Mechanical presses have production rates generally faster than those of hydraulic presses, since their maximum stroke rates are about $\sim 100 \text{ min}^{-1}$ and 10 min^{-1} , respectively (Beiss, 2010; Oberacker, 2012).

Hydraulic systems are generally best suited to producing large and/or thick compacts. Their maximum depth of powder fill is greater than in a standard mechanical press. Computer-controlled servo hydraulics allow very precise punch movements and to accurately control the pressing sequence of multiple punch tooling systems. Several closed-loop controlled axes are provided to activate the powder filling system and compaction units (rams, core rods, auxiliary platens, etc.). By this way, special parts with cross holes and undercuts, which cannot be made with conventional dies, can be produced (Oberacker, 2012).

Isostatic pressing can be used to produce small to relatively large powder compacts with good bulk density and uniformity for sintering. However, it is limited to relatively simple shapes and green machining is generally required, because of poor dimensional control, to achieve the desired size and shape of compacts. Uniaxial pressing ensures higher production rates and very large sizes, and in some cases complex parts can be formed to near-net-shape. A sort of calendaring has been recently introduced to produce large slabs (up to 10 m^2).

Isostatic Pressing

Cold isostatic pressing consists in compacting a dry or semi-dry powder in an elastomeric mold submersed in a pressurized liquid (Reed, 1995; Oberacker, 2012). Rigid tooling (e.g., a steel mandrel) is often combined with the flexible elastomeric mold to ease shaping. Typical forming pressures for ceramics are in the 20–200 MPa range. Isostatic pressing can be performed in two ways: “wet bag” and “dry bag” (Ewsuk, 2001; Oberacker, 2012). The wet bag route entails compacting a powder in a sealed elastomeric mold that is completely submersed in pressurized fluid (Fig. 3).

This route is used for low-volume production of specialty parts, for prototyping, and for research and development. The elastomeric mold is an integral part of the isostatic press in the dry bag route. Thus, the applied pressure is mostly biaxial. A major advantage of dry bag isostatic pressing is that it can be automated for high-volume production (Oberacker, 2012).

Uniaxial Pressing

Uniaxial die pressing consists in compacting powder to a prescribed size and shape within a rigid die cavity using one or more rigid plungers (Reed, 1995; Oberacker, 2012). Alternatively, dieless pressing can be performed on powders on a tape between two large

plungers. The tape is flexible and can be metallic or a polymeric composite. The dies and plungers used in uniaxial pressing are typically made of rigid materials that are hard and have good wear resistance. They can be coated with hard rubber to get a given texture. Typical production rates for die pressing, using pressures of 15–140 MPa, range from 1 to 300 parts per minute for advanced ceramic component and 7–12 m² per minute for ceramic tiles.

Die pressing can be accomplished with a single-action, dual-action, or floating die press (Fig. 4). A single-action anvil press has one moving punch, while a dual-action press has two or more moving punches. In the floating die press, most used in ceramic manufacturing, punches and die body can move independently. This allows to fabricate large pieces or more complex parts, including tapers, holes, and multiple steps. At the same time, it provides the flexibility to balance the forming pressure within different areas of the compact; thus, to minimize density gradients, in the pressed compact (Ewsuk, 2001; Oberacker, 2012).

Calendering

Calendering entails compacting a powder between two flexible tapes that pass through two rotating drums (compactors). It allows manufacturing of large slabs in a continuous way and with a high production rate. Tapes are typically metallic and provide a

smooth surface, but also structured tapes can be employed to get textured surfaces. Powder is laid on the lower tape and pressure is controlled by regulating tensor drums that impose the angle between the two tapes. Thickness is fixed by the light between compactor drums, while bulk density must be adjusted by the thickness of powder feed (soft layer). Actual size is determined after compaction by cutting the continuous sheet coming out from drums.

The Powder Pressing Process

A typical powder pressing operation has three basic steps: (1) filling the die with powder (or laying powder on the tape); (2) compacting the powder to a given pressure (or thickness in case of calendering); and (3) ejecting the powder compact from the die/drums.

Die Filling

The bulk density and packing uniformity of a granulate powder within a die (or on a tape) both influence the characteristics achieved after compaction and, eventually, the bulk density, microstructure, and properties of the final product after sintering (Reed, 1995; Glass *et al.*, 1995; Lannutti, 1997). The packing efficiency and uniformity achieved during die/tape filling are affected by the size distribution, fluency, and bulk density of granules as well as by the geometry/size of the die (Dinger and Funk, 1997). In general, narrow granule size distributions and/or small dimension of die cavities determine a lower packing density. Increasing aspect ratio (i.e., height/diameter) in small dies makes the variability in packing density to increase.

The die is usually filled by a volume-controlled feed shoe system. It consists of a bottomless box that slits over the open die and then is pulled back into a resting position. The powder, fed by a hopper, falls under gravity into the feed shoe. The tool movements can be controlled, in case of complex or thin-walled parts, to realize overfilling, suction filling, or contour filling, in order to optimize the uniformity in density distribution of the compacts. In fact, the packing density is reduced over a distance of 10–50 particle diameters from the die walls (Oberacker, 2012).

Granulates assume a hierarchical packing structure by filling the die (or laying on the tape). Porosity in this packing structure can be present at two levels (inside single granules or between granules) giving rise to four types of void (Oberacker, 2012; Soldati *et al.*, 2018b): (P1) the intragranular micro-porosity between the primary particles constituting the agglomerate; (P2) the cavity or large macro-pores inside the agglomerate; (P3) the intergranular voids between the granules; and finally larger packing flaws (Fig. 5).

Die wall effects can be minimized or eliminated if the die is sufficiently larger than the granule size. In general, smaller size granules should be used to fabricate parts of smaller dimension. For a typical, spray-dried alumina powder, the average agglomerate size should be smaller than the compact thickness and diameter, respectively, by 250-fold and 40-fold (Ewsuk, 2001).

The bulk density of a powder within the die is known as the fill density. It is usually in the range of 25%–40% of the true density of the granulated ceramic powder, considering only the inorganic constituents. Ideally, to avoid pressing defects, high fill densities are desirable to keep the compaction ratio (i.e., the pressed compact density divided by the fill density) below 2 in advanced ceramics, or below 2.5 in clay-based bodies.

Powder Compaction

During powder compaction, granule rearrangement, deformation, and consolidation of the particulate assembly are promoted by the applied pressure. This process induces an increase of particle coordination number, green bulk density, and compact strength with increasing compaction pressure (Frey and Halloran, 1984; Zheng and Reed, 1988). Overall, higher values of green density are

Fig. 5 Scheme of die filling with granulate: different kinds of porosity.

obtained with a higher fill density (hence a better powder fluency). This compact will sinter to a higher end point density with a lower shrinkage (Glass *et al.*, 1995; Ewsuk, 2001).

Although common in pressed powder compacts, density gradients must be minimized, because they contribute to differential sintering and shape distortion (Glass and Ewsuk, 1997; Oberacker, 2012) leading eventually to defects that limit the performance and reliability of the finished product. Density gradients occur at two scales that are important in powder compaction: (1) large-scale gradients, consequent to nonuniform die filling and/or applied load during powder compaction (Reed, 1995; Lannutti, 1997); and (2) small-scale density variations due to flaws in powder, hollow granules, and/or insufficient deformation during compaction (Shinohara *et al.*, 1999). To prevent such defects, granules should be strong enough to pack more efficiently (permitting a significant rearrangement prior to deformation/fracture) but weak enough to produce a uniform microstructure (breaking down, deforming, and knitting together during compaction) (Glass *et al.*, 1995; Oberacker, 2012). Powder compacts are comprised of discrete particles, and the stress is transmitted non uniformly through particle–particle contacts. Account must be taken of the stress network, where granule/particle bridges may support stresses higher than the applied stress, and that shield localized regions between the bridges from the applied stress (Glass and Ewsuk, 1997; Ewsuk, 2001).

Die wall friction must be controlled during pressing to minimize pressure gradients that can create defects (density gradients and/or cracks in a powder compact). Friction can be controlled through the design of the die and the pressing process or by internal or external lubricants (Balasubramanian *et al.*, 2002b). Die wall friction can be minimized with smooth surface dies and carbide tooling. Frictional effects are also minimized in simple shape, low aspect ratio parts, and by dual-action pressing in preference to single-action pressing. Deleterious die wall frictional effects also can be minimized by isostatic or biaxial pressing in preference to uniaxial die pressing (Reed, 1995; Oberacker, 2012).

Compaction Mechanisms

Several factors play an important role in determining compaction behavior: pressing conditions, granule characteristics, hierarchical packing structure, and discrete particle–die and particle–particle interactions. Pressure–density plots allow relating the compaction behavior to processing parameters and powder features (Fig. 6). Such compaction response diagrams show how the bulk density of a compact changes as a function of the applied load. Three compaction regimes are usually identified, as stages of nominally linear response when data are plotted on a log–pressure scale (Glass and Ewsuk, 1997; Carneim and Green, 2001; Oberacker, 2012):

Stage I, bulk density slightly increases from the value of poured density to a random packing density, corresponding to the first breakpoint.

Stage II, bulk density rapidly increases by progressive downsizing of intergranular macro-pores up to the second breakpoint.

Stage III, bulk density increases by a slower rate, as intergranular pores are sealed off and any further densification proceeds by closure of the larger intragranular micro-pores.

Compaction response diagrams provide general information on compaction and specific information on granule stiffness and deformability. Compaction is interpreted to occur primarily by rearrangement in mutual position of granules in the stage I, and mostly by granule deformation, cracking and knitting in the stages II and III (Reed, 1995; Carneim and Green, 2001; Carneim and Messing, 2001; Oberacker, 2012). First the large pores are eliminated (intergranular porosity P3 and inner cavity P2) during stage II, then smaller pores (compressible fraction of intragranular porosity P1) are closed during stage III. Various factors control the extent of densification due to each mechanism, such as localized pressure, and characteristics of granules and primary particles. Typically, granulated ceramic powders are compacted to a point corresponding to the beginning of stage III (Niesz, 1996).

Granule Characteristics and Compaction

Ideally, granules should deform and fracture during compaction to eliminate the intergranular porosity (present in the die fill) and subsequently knit together, resulting in a homogeneous microstructure with no remnants of the original granule structure. In

Fig. 6 Compaction response diagram showing a typical bulk density to applied pressure evolution for a spray-dried powder (porcelain stoneware). Three compressional stages are outlined (see text for details) separated by two break points.

Fig. 7 Example of rearrangement, deformation, breakdown and knitting of spray-dried granules at increasing applied pressure. Powders for porcelain stoneware tile production.

particular, the granule yield strength, referred to the first break point, is related to fracture strength (Carneim and Green, 2001; Oberacker, 2012). Stiffer granules have a higher yield strength and can undergo a more extensive rearrangement at low compaction pressures to increase packing efficiency and density uniformity prior to granule deformation/fracture. However, if too stiff, the granules will not completely deform to eliminate large inter-granular porosity after compaction. Excessively hard granules can result in defects, such as a lower compact density after pressing, or large residual pores, or even a too rough surface finish. On the other hand, soft granules can produce a higher density compact by readily deforming during pressing. Nevertheless, if too soft, they will not rearrange enough in stage I to eliminate packing defects present after die filling. Compacting soft granules with strong packing heterogeneities, stemming from poor die filling, can give rise to severe density gradients after pressing, and cracking after sintering.

Granule stiffness is controlled by many factors, including the organic additives used for granulation, moisture content, and granule size (Lannutti, 1997; Shinohara *et al.*, 1999; Walker *et al.*, 2000; Uppalapati and Green, 2006). In general, weaker granules are produced with softer organic binders having a lower glass transition temperature, T_g . To make weaker granules, plasticizers can be used to lower the T_g of a binder system; moisture can act as a plasticizer as well (Shinohara *et al.*, 1999; Lannutti, 1997; Carneim and Messing, 2001).

Along with general information on compaction, bulk density to applied pressure diagrams provide specific information on granule stiffness and deformability. However, they need to be complemented with other techniques to complete a comprehensive assessment of compaction. For instance, pressed and fracture surfaces of green compacts, formed at increasing load, can be observed to characterize microstructural evolution during powder compaction (Niesz, 1996; Soldati *et al.*, 2018b). In particular, granule deformation and breakdown can be followed while large intergranular packing voids are downsized to produce a homogeneous microstructure (Fig. 7). Pressed surfaces formed at low pressures clearly exhibit the granule structure, intergranular packing voids, and some degree of granule deformation to eliminate those voids. With increasing pressure, granules knit together and the compact strength increases, as the fracture mode changes from intergranular to intra-granular. At higher pressure, compacts show fewer and fewer granule relics and microstructure becomes more homogeneous.

Ejection

In general, a pressed powder compact must be strong enough to withstand the forces exerted on it during ejection from the die. Main issues with ejection are green compact strength, die wall friction, and elastic springback. Ejection defects can be ideally avoided with a combination of a high green compact strength and a low ejection pressure. Internal lubricants and die wall lubricants are often used to lower the ejection pressure (Balasubramanian *et al.*, 2002b).

A critical factor in ejection is springback, i.e., the expansion of the compact upon ejection from the die. It is determined by the elastic energy stored in the compact during the compression. Springback can be as much as 0.5% up to 1%, with greater expansion occurring with higher pressures. In uniaxial compaction, in particular, a differential springback usually occurs, since the axial expansion is greater than the radial. Although some springback is needed to separate the compact from the die without sticking, excessive expansion can lead to catastrophic flaws within the compact (Reed, 1995; Ewsuk, 2001). In addition, a too high differential springback (i.e., perpendicular vs. parallel to the pressing direction) is also problematic, especially in case of high pressures and trapped gasses within the powder compact. Problems can be minimized by recourse to appropriate organic binders to get good green strength at low pressure, and by taking care that air can escape from the compact during pressing. Defects due to differential springback can be avoided by ejecting the compact under “punch hold-down”, which maintains axial pressure on the compact during ejection (Ewsuk, 2001).

Compaction Defects

Many of the defects observed in powder compacts are defects that manifest upon ejection. They originate from inadequate values of powder properties or processing conditions (Ewsuk, 2001; Balasubramanian *et al.*, 2002a,b) as summarized in Table 2.

Table 2 Typical defects in ceramic powder pressing: nature and causes

Defect	Description	Poor green strength	High springback	High die-wall friction	High specific pressure	Poor punch-die tolerance	High compaction ratio	High stroke rate
End-capping	Cone-shaped separation at the pressing punch face and into the compact	X	X	X	X			
Ring-capping	Ring separation at the outer edge of the punch face and out of the compact		X			X		
Lamination	Periodic circumferential cracks perpendicular to the pressing direction	X	X	X	X			
Vertical cracks	Elongated cracks parallel to the pressing direction	X	X				X	X

**Fig. 8** Yield surfaces for increasing density (D) on the stress plane (p - q) and expression of stresses.

Compaction Modeling

Numerical modeling provides powerful and promising tools to better understand and control, once experimentally validated, powder packing and compaction, so improving the earlier analytical micromechanical models (Brewin *et al.*, 2007; Sinka, 2007). These tools are distinguished as either: *phenomenological models*, aimed to simulate the pressing of real parts by finite element methods (FEM), which are based on continuum soil mechanics, or *micromechanical models*, which calculate the interactions between powder particles to derive the bulk powder properties; two approaches can be followed (Harthong *et al.*, 2009): discrete element method (DEM) and meshed DEM (MDEM). However, a combination of these different methods is needed for an effective modeling. Ideally, MDEM should be used to derive force–displacement laws for DEM, whilst DEM simulations should be exploited to get suitable constitutive equations, by which FEM calculations should simulate the compaction of a real compact (Oberacker, 2012).

In the phenomenological models, a constitutive model can be combined with numerical modeling by FEM to get realistic predictions of the density gradients in a powder compact after pressing. The most often-used model in FE simulations is the Drucker–Prager Cap model (Sinka and Cocks, 2007; Pizette *et al.*, 2010) by which the material response is expressed in terms of stress and strain invariants (e.g., hydrostatic pressure, p , and equivalent stress, q) that amount to a yield surface on the p - q plane (Fig. 8). This surface depends, along with the stress invariants, mainly on the bulk density of compacts, as shown by its expansion with densification. The compact deforms elastically at stress levels within the yield surface but, when the stress reaches the yield surface, plastic deformation takes place. The strain vector (i.e., the incremental deformation) is in the direction normal to the surface: densification ensues from a positive component in the p -direction, while a negative component will turn into a shear failure.

The main applications of the phenomenological models are in the tool design for complicated multilevel parts. The required constitutive laws can be derived from hydrostatic and triaxial compression tests (Shridar and Fleck, 2000; Wikman *et al.*, 2006; Sinka and Cocks, 2007). Additionally, these same tests have been used to assess other bulk properties (e.g., pressure-dependent bulk and shear modulus and Poisson's ratio) necessary to model ceramic powder compaction. Moreover, the die wall friction coefficient can be realistically estimated, given that good powder data be available for input into the model. Eventually FEM compaction modeling may be employed, in combination with readily measurable powder characteristics, to address the design and development of more performing powders.

The micromechanical approach can be successfully applied to reproduce either particle rearrangement (DEM models) or powder compaction up to high densities (MDEM) with some limitations. DEM calculations are based on a local model of the contact behavior between two particles that assumes no interaction in the individual contact zones. Although both tangential

forces and contact friction mechanisms are taken into consideration, their application is limited to stage I and stage II of powder compaction. MDEM is based on FEM calculations of meshed discrete particles arranged as 2-D or 3-D random packings. Computing time restrictions limit simulation to assemblies of approximately 100 particles.

In particular, the stage I of compaction can be modelled by DEM for various stress states and agglomerate strength and size. In addition, the effect of particle size and polydispersity, agglomerate density, and attractive interparticle forces on die filling can be considered. Simulations provide packing configurations, and microstructure development as a function of fundamental material parameters and boundary conditions (Skrinjar and Larsson, 2004). DEM simulations suggest that only some granules support external pressure during early compaction, hence the force is transmitted non homogeneously during packing. About the stage II, DEM was applied to both aggregated powders with primary particles bonded by solid bridges and agglomerated powders with weakly bonded primary particles. Results support the role of granule cracking in the compaction mechanism by contact deformation (Martin and Bouvard, 2006; Balakrishnan *et al.*, 2010).

Introduction

The reliability of ceramic materials can be improved using colloidal synthesis and processing techniques (Lange, 1989; Moreno *et al.*, 1998). Colloidal casting processes are used to produce high performance ceramics with a complex shape from a specially formulated slurry that is typically composed of a broad range of raw materials including oxides, carbides, nitrides etc. (Schilling, 2001). Processing of ceramics into useful shapes needs to start with ceramic powders (Askeland and Phule, 2003) and requires intimate control of solution chemistry and particle dispersion in suspensions for manufacturing of bulk forms (Bell *et al.*, 2015).

The colloidal shape forming methods can be classified as slip casting (Schilling and Aksay, 1991; Schilling, 2001), tape casting (Blugan *et al.*, 2007), dip coating (Scriven, 1988), gel casting (Young *et al.*, 1991), centrifugal casting (Huisman *et al.*, 1995b), freeze casting (Deville, 2008), injection molding (Fanelli *et al.*, 1989), direct coagulation casting (Graule *et al.*, 1994; Si *et al.*, 1999), and colloidal iso-pressing (Yu and Lange, 2001). A fabrication of a ceramic complex shape with colloidal processing typically involves (1) powder synthesis, (2) suspension preparation, (3) consolidation into the desired shape to form (known as a green body), (4) removal of solvents, and (5) densification using firing or sintering under a controlled heat treatment and atmosphere (Lange, 1989; Lewis, 2000). This process requires a colloiddally stable environment, where each component is properly dispersed in order to avoid unintentional heterogeneities (or defects) during the fabrication process (Lewis, 2000; Bell *et al.*, 2015). Subsequently, the material can be exposed to numerous additional operations such as grinding, polishing, or machining to get the final shape for a specific application.

In other conventional techniques of ceramics shaping such as dry pressing, starting powders must be carefully conditioned by wet mixing and consecutively need to be dried, which can lead to undesirable agglomeration. However, in colloidal techniques, green bodies are obtained directly from suspension, which in turn lead to high uniformity of the final products and considered as one of the major advantages of the colloidal casting systems.

Slip Casting

Slip casting the one of the oldest and most common industrial green forming techniques among colloidal casting processes that is typically used for fabrication of widely used ceramics such as porcelain, tableware, sanitary ware, structural tubing, automotive, and biomedical components (Schilling, 2001; Bengisu, 2013).

Slip casting is a batch process and its basic steps are represented in Fig. 1. Initially, an aqueous slurry of fine ceramic powders is poured into a permeable mold with micro-pores (Fig. 1(a)). Subsequently, partial drying of the slurry is achieved, i.e., liquid (typically water) begins to move out from the slip through the porous mold walls, under the effect of a capillary action (Fig. 1(b)). This leads to formation of a thick layer or body of densely packed particles along the mold walls. After desired thickness of the body is reached, the remaining slip is drained from the mold (drain casting, Fig. 1(c)). Production of shell and hollow components are typically achieved by partial drying of the slip and subsequent draining of the remaining liquid (Bengisu, 2013). In production of bulk and solid pieces, slip is continuously added/poured until solid cast forms and called as solid casting (Schilling, 2001). Separation of the solid body from the mold typically can be achieved easily as a result of shrinkage upon drying (Fig. 1(d)).

The slip casting process relies on numerous control parameters including casting rate, rheology of the slurry during filling and draining, density and yield strength of the cast, shrinkage and release properties of the cast when removing from the mold. The colloidal and rheological properties of aqueous powder slurries are important factors that need to be carefully examined. Ideally, casting slurries should be pseudoplastic with a viscosity that is sufficiently low (usually $< 2 \text{ Pa s}$ at a shear rate of $1\text{--}10 \text{ s}^{-1}$) for ease of handling during pumping and mold filling. High solid loadings are also advantageous for enhanced filtration during slip casting. Furthermore, the density and yield point of the slurry needs to be high enough to avoid differential settling of the particles in the slurry. Thus, to address these requirements polydisperse particle size systems and organic polymers (dispersants, plasticizers, binders, viscosity modifiers) are suggested to be utilized (Lange, 1989).

Water is the most typical liquid in slurry preparation, however, some of the powders such as MgO , CaO , Si_3N_4 , and AlN , can react with water. In such cases, alcohols, trichloroethylene, and methyl ethyl ketone can be used instead of water (Reed, 1995; Bengisu, 2013) as a solvent.

Another critical point is the packing density of the cast, which needs to be uniform to mitigate non-uniform shrinkages as such shrinking can in turn lead to crack formation during drying, debinding and sintering steps (Schilling, 2001). Additionally, the diffusion of organic polymers to the capillaries of the molds can cause severe problems and affect the reproducibility of the casting process and can damage the mold.

Fig. 1 Basic steps of slip casting process (a) filling of the mold with slip, (b) removal of liquid (due to capillary action) and formation of a cast layer along the mold walls, (c) draining of the excess slip from the mold; (d) green body removal after partial drying. Reproduced according to Askeland, D.R., Phule, P.P., 2003. *The Science and Engineering of Materials*, fourth ed. Springer, p. 639.

Mold is a critical component of a slip casting process, which is in charge of capillary withdrawal of the liquid through its pores (Hampton *et al.*, 1988; Francis and Roberts, 2016). The most common mold material is gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), produced by the reaction of plaster of Paris and water according to Eq. (1).

As a permeable mold, gypsum molds possess 40%–50% porosity and are highly advantageous due to its low costs, high availability, small pore size, good reproducible water adsorption properties, smooth surface, and wide variety of shapes. The pores of gypsum crystals are interconnected with capillaries (typical diameter range of 100 nm to 5 μm), and filled with water during cast process. The pore size and porosity depends on water/plaster ratio. The higher water/plaster ratio results in higher porosity and larger pores, which in turns results in higher water adsorption capacity, however strength of the molds decay in parallel. Furthermore, gypsum molds typically have low thermal shock resistance and desiccation of the gypsum is observed when heated above 40°C during drying (Reed, 1995). The crystal structure and setting time of the gypsum molds depend on temperature, mixing time and electrolytes in the water, and should ideally be taken under control for reproducibility of molds and slip casting process (Schilling, 2001; Reed, 1995).

Even if gypsum/plaster molds are suitable for machining and considered as a cost-effective option in slip casting, they possess a limited service life (80–100 maximum casts) and exhibit long drying time for removal of the water due to their low wear resistance and limited temperature stability. Therefore, mass production of commonly used ceramic parts can preferably done by using durable polymer molds (Kryuchkov and Neklyudova, 2015). The polymeric materials with an open pore structure can show high water permeability, mechanical, and fatigue performance with less deformation and long service life (depending on the type of the material utilized). Polymethyl methacrylate (PMMA)-based porous materials are the most widely used polymer molds that can shorten casting period due to mitigation of the drying step. In polymeric molds the dewatering can be achieved through air-purging system (Inoue *et al.*, 1988; Ergün *et al.*, 2004).

The major factors affecting the growth rate of a cast are reported to rely on (1) the permeability to water of the cast layer, (2) the specific gravity of the slip, and (3) the suction pressure of the mold (Adcock and McDowall, 1957).

Numerous theoretical and experimental studies have been performed to estimate the mechanics and behavior of slip casting process (Kocatopce, 1946; Adcock and McDowall, 1957; Haerle and Haber, 1995; Banno *et al.*, 1999). The casting layer thickness, L , can be estimated with the cast layer growth rate according to casting kinetic models (Adcock and McDowall, 1957; Schilling and Aksay, 1991; Bengisu, 2013), as defined in Eq. (2):

$$L = \left\{ (2P_m g E^3 t) / [5S^2 \eta (\gamma - 1)(1 - E)^2] \right\}^{1/2} \quad (2)$$

$$P_m = S_m \sigma \cos \gamma \quad (3)$$

where E is the porosity of the casting layer, t is time, S is the surface area of suspended particles, η is the viscosity of the slip, g is the gravitational acceleration, and γ is the volume of the slip containing a volume equals to $1 - E$ of solids. P_m is the pressure drop across the mold (estimated according Eq. (3) by the Laplace equation), S_m is the specific surface area of the mold, σ is the surface tension of the liquid, and γ is the contact angle ($\cos \gamma = 1$ for plaster of Paris in contact with water). The casting rate is constant with time

(L vs $t^{1/2}$) when the mold suction and resistance reach to constancy and indicate presence of a uniformly dense cast layer if a linear plot is obtained (Reed, 1995; Schilling, 2001). Deviations in the linear plot are indicative of presence of large agglomerates as a result of gravity sedimentation during slip casting or changes in rheological properties of the slip with time (Schilling, 2001).

To manufacture desirable and reproducible complex ceramic shapes with slip casting, numerous parameters such as particles size of the starting powders, viscosity, mold type, casting time and temperature, pH, and additive organic polymer properties need to be carefully controlled. Slip casting has a wide range of application areas from traditional ceramic parts like kitchenware or porcelain products to gas turbine rotor or aluminum titanate exhaust port liners for engines (Kennard, 1986; Bell *et al.*, 2015). However, this technique is a batch and relatively slow process and suitable for limited production elements (Bengisu, 2013).

Non-traditional casting processes such as pressure casting, vacuum casting and centrifugal casting on the other hand offer increased filtration rate, filling rates and uniformity that in turn results in faster production rates.

Pressure Casting

Pressure casting is an automated production process where an external pressure is applied to increase the filtration rate for large-scale production of complex and thicker parts in a shorter production cycle compared to conventional slip casting. Unlike slip casting, where filtration occurs by capillary action (~ 0.1 MPa) (Reed, 1995), pressure casting is achieved by application of an external pressure that typically varies from medium (0.3–0.4 MPa) to high (up to 4 MPa) levels depending on manufactured material size and mold type (Buschow *et al.*, 2001).

Pressure casting process is working in a similar principle with pressure filtration process, where liquid is removed through pressing the slip into a porous mold serving as a filter (Bengisu, 2013). A schematic diagram of pressure casting is shown in Fig. 2. Pressure casting technique can decrease the production time up to an order of magnitude that in turn results in a significant decay in the fabrication costs. In the study of Gainer and Carter, it was reported that application of a slip pressure up to 1.5 MPa led to increase of the cast thickness by factor of 2–3 and the casting time of a ~ 1 cm thick wall decreased from 1 to 2 h to less than 20 min (Gainer and Carter, 1964). Furthermore, drying of plaster molds is one of the most time consuming and labor-intensive steps while occupying large floor spaces in conventional casting systems. In pressure casting these problems can also be avoided (Buschow *et al.*, 2001).

Fig. 2 Schematic diagram of pressure casting process. Reproduced according to Bengisu, M., 2013. Engineering ceramics. Springer Science & Business Media, p. 123.

Conventional molds (gypsum molds) prone to fracture at high pressures, therefore high strength polymeric molds are needed in pressure casting. This leads to relatively higher capital costs when compared to conventional molds, however, enhanced production levels enables pressure casting still an economically favorable option (Schilling, 2001). Polymeric molds are more resistant to possible chemical reactions between mold and metal ions metal ions in the slip and possess a longer lifetime (can withstand to $\sim 10,000$ cycles) than that of plaster molds (~ 100 cycles) (Lyckfeldt *et al.*, 1994; Bengisu, 2013). Another drawback of the plaster molds is the presence of Ca^{2+} in the cast detected after interaction of the cast surface with the mold which in turn causes a contamination in the green bodies (Moreno *et al.*, 1998). Polymeric molds are not prone to surface wear and providing proper fit of the slip to the mold with an increased consistency in the edges and sharp corners, and decreased surface roughness of the greenware when compared to conventional molds. In pressure casting, the process relies on the degree of the pressure (external pressure gradient) used rather than extraction of water with capillary suction from the molds (Fennelly and Reed, 1972). This bypasses the need of additional mold drying step and accelerates the production rate. More importantly, with its automated production operation, fluctuations in the quality of manufactured parts are reduced and uniform greenware with less moisture can be produced with pressure casting.

Vacuum Casting

In vacuum casting, the capillary suction of a mold is increased by applying external suction under vacuum conditions in order to create pressure gradient for faster casting rate. Vacuum casting was previously widely used in production of standard samples and porous refractory insulation materials (Reed, 1995). The permeable preform, connected to a vacuum line, is submerged and kept in a slurry, until desired thickness is reached.

After utilization of silicon rubber as a mold material, vacuum casting has started to be considered as a versatile and rapid indirect soft tooling technology for production of small series of functional plastic parts i.e., high quality prototypes or end-use products, with a high degree of dimensional accuracy. (Tang *et al.*, 2007; Abu Bakar *et al.*, 2009; Strube *et al.*, 2014; Wortmann *et al.*, 2018). It is an indirect technique since a master pattern is required prior to mold tooling (Tang *et al.*, 2007).

Fig. 3 represents an example of the vacuum casting process that is used in manufacturing of micro-gears and its micro-molds (Tang *et al.*, 2007). Initially, a master pattern of the desired product is produced typically using stereolithography or laser sintering (Wortmann *et al.*, 2018), with a high-quality surface finish. In parallel, a silicone mold is produced by casting silicone around the master copy under vacuum conditions to mitigate the presence of air bubbles. After hardening of the silicone mold, the mold is cut

Fig. 3 Manufacturing steps involved in vacuum casting. Reproduced according to Tang, Y., Tan, W.K., Fuh, J.Y.H., *et al.*, 2007. Micro-mold fabrication for a micro-gear via vacuum casting. *Journal of Materials Processing Technology* 192–193, 334–339.

according to pre-defined parting planes. Subsequently, master pattern is removed to obtain the micro-mold by leaving a cavity to be used in production of copies. Besides silicone rubber, numerous types of plastic materials including polyurethane, rubber, nylon, and polycarbonate can be used in vacuum casting systems (Abu Bakar *et al.*, 2009).

Vacuum casting can be used in casting of resins, plastic, and metals due to high chemical resistance characteristics of silicone rubber molds (Tang *et al.*, 2007). Furthermore, this technique is widely applied in medical area (Ng *et al.*, 2009), part miniaturization for production of polymer biomicrosystems (Denoual *et al.*, 2005) and manufacturing of ceramics (He *et al.*, 2002). Further studies have been performed in micro-electro mechanical (MEMS) fabrication for production of optical switching, chips, micro-fluidic channels (Denoual *et al.*, 2006; Wang *et al.*, 2013). Even if vacuum casting has a significant potential in manufacturing of plastic functional parts, there are still some challenges existing on mass production.

Centrifugal Casting

Centrifugal casting is originally known from cement industry from 1978, as being the most common method used to manufacture tubes and pipes in cement industry (Glasser and Zhang, 2001; Kaufmann, 2004). Centrifugal casting involves solid-liquid separation by spinning a mold in lab-scale centrifuge in order to accelerate the sedimentation of colloidal suspension for the compaction of powders. The molds used in centrifugal casting do not need to be porous and can be fabricated from different metals and plastic materials (Buschow *et al.*, 2001; Schilling, 2001).

In this technique, the mold is located at the bottom of centrifugal bucket that can produce the centrifugal action in the direction of the mold. Centrifugal force can accelerate the casting speed and significantly shorten the casting time. Different from slip casting, the liquid in the slurry is removed from the top of the cake in this technique. Centrifugal casting technique allows manufacturing of thicker parts in a faster manner compared to other casting methods.

Centrifugal casting is one of the least common industrial casting technique in ceramics due to the following drawbacks: (1) differential settling during the consolidation stage and (2) significant gradients in compaction stress observed within the cake at different radial distances from the center of the centrifuge (Buschow *et al.*, 2001; Bengisu, 2013). These factors result in gradients also in packing density and formation of subsequent shrinkage cracks during drying and debinding. The compressibility problems can be addressed by avoiding flocculated slips (Schilling *et al.*, 1998; Buschow *et al.*, 2001). To avoid segregation problems, consolidation is suggested to be in the flocculated or in the coagulated state or utilize highly concentrated dispersed suspensions (Huisman *et al.*, 1995a,b; Schilling *et al.*, 1998; Buschow *et al.*, 2001).

Centrifugal casting is also a common method for obtaining functionally graded materials (FGM) and manufacturing of layered micro-composites through the sequential casting of different slip formulations (Marshall *et al.*, 1991; Bengisu, 2013). The layer thickness can be arranged via controlling the centrifuging speed and the solid concentration in the slurry (Marshall *et al.*, 1991). Mainly composite materials such as SiC reinforced Al-based FGMs or metallic materials having high differences of density and low solubility on different phases can also be produced with centrifugal casting (Chirita *et al.*, 2008).

Alternatively, the slip is located in a hollow cylindrical plaster mold and rotated around its axis to manufacture tubular or axisymmetrical bodies (Bengisu, 2013). For instance, rings, tubes, pipes, and large motor housings are typically produced using centrifugal casting (Campbell, 2015).

Gel Casting

Gel casting is one of the ceramic forming processes that was developed to overcome challenges like long binder burnout times, size and geometry limitations, or non-uniform density issues of conventional complex shape forming techniques. Gel casting was first developed in Oak Ridge National Laboratory (ORNL), USA in 1980s by bringing together traditional slip casting process and polymer chemistry.

Gel casting process is completely based on organic materials. Here, initially a suspension of the fine ceramic powders mixed with organic monomers composed of organic dispersants and binders is prepared. The prepared slurry is subsequently poured into a nonporous mold and kept for in situ polymerization or gel formation to obtain a green body with the shape of the mold cavity. After gelation, the material is removed from the mold for drying, binder burnout, and finally sintering. The basic manufacturing steps of gel casting process is summarized in Fig. 4.

It is important to distinguish gel casting and sol-gel process. Sol-gel process is previously developed by Yoldas (1992) in which solid is produced as a part of the process in the form of an inorganic gel with a low solid loading. On the other hand, gel casting is comprised of commercial powders in a dispersion (with a high solid loading) containing organic monomers that are used for polymerizing the dispersion into an organic gel in order to hold the powders together in the desired shape (cavity of the mold) (Omatete *et al.*, 1997).

In gel casting, ceramic powders are dispersed in an aqueous monomer solution that is composed of a solvent, chain former monomers, crosslinking agents, free-radical initiators, and a catalyst plus surfactant. Reactive organic monomers, used for polymerization, are one of the key components of this process. Similar to other polymerization systems, gel-casting ingredients are reactive chemicals and can cause health and environmental problems with their release or exposure to workers (Janney *et al.*, 1998). Therefore, monomer selection in gel casting requires special attention.

Fig. 4 Manufacturing steps involved in gel casting. Reproduced according to Omatete, O.O., Janney, M.A., Nunn, S.D., 1997. Gelcasting: From laboratory development toward industrial production. *Journal of the European Ceramic Society* 17 (2–3), 407–413.

Both aqueous and non-aqueous solutions can be used in gel-casting, however, aqueous systems i.e., water as a medium/solvent, are highly preferred due to environmental concerns. In aqueous gel casting acrylic acid and acrylamide (AM) were initially widely used as a monomer together with N,N'-methylenebisacrylamide (MBAM) as a crosslinker. Even if AM system enabled advanced ceramics products, AM monomer is neurotoxic. Therefore, many attempts were done to replace AM with a less toxic and safer

monomer. In this regard, low toxic methacrylamide was started to be utilized in later stages of this process. In the study of Janney *et al.* it was reported that MAM-MBAM monomer systems produces green bodies with a sufficient strength for further machining (Yang *et al.*, 2011). Hydroxymethylacrylamide (HMAM), N-vinyl pyrrolidone (NVP), and methoxy poly (ethylene glycol) mono-methacrylate (MPEGMA) (Bengisu, 2013) are some of the monomers that are widely used in gel casting systems. As crosslinking polymers MBAM, 2-hydroxyethyl methacrylate (HEMA), poly(ethylene glycol) dimethacrylate (PEGDMA), temperature activated crosslinking polymers such as agarose and carrageenans and crosslinking of polymers with metal-ion complexation route are highly preferable (Yang *et al.*, 2011; Bengisu, 2013). Additionally, ammonium persulfate (APS) together with tetramethylethylenediamine (TEMED) are typically used to catalyze the polymerization and crosslinking reactions.

In gel casting, narrowly dispersed submicron ceramic powders are preferred in the suspensions to enable uniform grain growth during sintering and obtain high homogeneity in the end material. Therefore, it is crucial to have high solid loadings, up to 50 vol% solids in a slurry, which is known to minimize the shrinkage and deformations during drying and sintering. Such high solid loadings also require further consideration in rheology of the slurries i.e. utilization of dispersants, to avoid problems during pouring of the fluid to the mold. Consequently, the prepared slurry is first poured into the complex shaped molds, then polymerized and crosslinked in situ to form polymer-water gel, which gets the form of the mold. There is a wide variety of mold materials for gel casting. Molds for gel casting can be made of metals, glass, wax and plastics, and only limited with the ability by the design of the mold shape.

In the next step, the gelled parts need to be dried under controlled conditions. Drying is the bottleneck of gel casting since it is the slowest and most critical step. The inner stress in the green material is mostly caused during transformation from suspension to green body or during drying stage. To avoid formation of cracks, drying of the gels needs to be conducted initially under relatively high humidity conditions (>90%) which is prolonging the drying step. Upon shrinkage in the body stops, the drying temperature is increased while decreasing the relative humidity. The burnout of the binders also needs to be done with slow heating rates to avoid problems that might be caused by carbonaceous residuals in the final material. The burnout temperature is slurry specific and depends on the ceramic powders and monomers used.

Gel casting is a well-established colloidal processing technique for manufacturing of high performance ceramics in a short time with high yields, a high green strength (allowing machining operations after drying), a high reproducibility, and low-cost machining. It has been widely applied in the industry for production of highly porous ceramic materials and near net complex shaped ceramics including rutile capacitor, thin-wall tube, turbine rotors, refractory nozzle, and microbeads (Yang *et al.*, 2011).

Introduction

Processing of most advanced ceramics from powders requires high degree of control to obtain desired microstructural characteristics and producing less-defective components from powders at lower costs. Selection of the appropriate processing technique depends on the raw materials, the shape and the number of pieces to produce.

Wet processing routes allow a better control of powder particles interactions in suspension, a greater homogeneity of particle packing and the achievement of final microstructures with less defects. Consolidation of colloidal suspensions into dense and homogeneous green bodies is a main characteristic of colloidal processing. As compared to dry processing techniques, colloidal processing has played a major role in the development of ceramic components with enhanced properties, capabilities and reliability, due to an improved control of the structure of compacts (Lewis, 2000). Besides some drawbacks, such as the low production rates, colloidal processing presents advantages over other techniques. The possibility to avoid aggregates and a better dispersion of the powder in a low viscosity medium enables to attain a better control of the microstructure and reproducibility of processed bodies with complex shapes and at low cost.

Processes such as slip casting, pressure casting, centrifugal casting, direct coagulation casting, tape casting, gel casting, injection molding and electrophoretic deposition are examples of colloidal processing methods. Among the several processes, three main routes for improving the ceramic processing of solid green bodies by using powder suspensions can be considered: (1) consolidation of the suspending medium – Gel Casting; (2) centrifugation – Centrifugation Casting and (3) flocculation/coagulation of the particles – Direct Coagulation Casting (DCC).

As one of the colloidal forming methods for near-net shape ceramics, direct coagulation casting (DCC) is characterized as a no or low organic binder involved (an advantage over gel casting process), high mechanical strength and high reliability of the ceramics.

Our main purpose is to analyze the process of Direct Coagulation Casting (DCC), reviewing the basic concepts supporting it and the developments introduced to improve the properties of the processed bodies by this technique.

Fundamentals of Direct Coagulation Casting

Electrical Double Layer

Powder particles in aqueous suspension develop an electric charge on their surface by the adsorption of charged species, either potential determining ions H_3O^+ and OH^- or other charged ions (specifically adsorbed). The positively or negatively charged particle surface will be balanced by the ions of the suspending medium and the total charge in the system is zero. Due to ionic attraction and repulsion an electrical double layer (EDL) is formed nearby each particle surface, that it will be surrounded by counter-ions (ions of the medium with charge of opposite signal of the surface) and co-ions (with charge of the same signal as the surface). High counter-ion density is localized on the surface and diffuse (co- and counter-ion) layer extends into the solution.

When pH of the medium is changed the amount of adsorbed species on particle surfaces varies and there is a value where the amount of both positive and negative types is equal, the isoelectric point of the powder (IEP). Therefore, the presence of the surface charges determines the electric interaction potential between the particles and the neighborhood ions of the medium.

Stern model for the EDL considers that the variation of the electric potential has two regimes: (1) first, near the particles surface, in the so-called Stern layer, there is a linear decrease of the potential, from a maximum value at the particle surface down to the Stern potential and; (2) after that, it shows an exponential decay with the increase of the distance to the surface, that is in the diffuse layer. If ψ_δ is the electric potential in the Stern layer and δ the thickness of the Stern layer, the double layer thickness becomes

$$\kappa^{-1} = \left[\frac{4\pi e^2 \sum n_i z_i^2}{\epsilon \epsilon_0 K_B T} \right]^{-1/2} \quad (1)$$

with $I = \frac{1}{2} [\sum n_i z_i^2]$ the ionic strength of the medium. In this equation, n_i is the ion concentration, z_i the valence of counter-ions; ϵ the electric permittivity, ϵ_0 the vacuum electric permittivity, e the electron charge, K_B the Boltzmann constant and T the temperature.

In the diffuse layer the potential decays exponentially and can be explained according to the Debye-Hückel equation:

$$\psi(x) = \psi_\delta \exp^{-\kappa(x-\delta)} \quad (2)$$

Fig. 1 Total curve of interaction potential between particles in a suspension vs. distance, according to DLVO theory. Reproduced from Balzer, B., Gauckler, L.J. 2003. Chapter 5.5 – Novel colloidal forming technique: Direct coagulation casting. In: Somya, S., Aldinger, F., Claussen, N., *et al.* (Eds.), Handbook of Advanced Ceramics: Materials, Applications, Processing, and Properties. Volume 1: Materials Science. Academic Press; Elsevier Inc., pp. 435–458.

It is seen that it depends mainly on the Stern potential and on both the Stern and the double layer thickness, which is controlled by the characteristics of the suspending medium i.e., through its ionic strength (Gauckler *et al.*, 1999). EDL thickness decreases with the increase in the ionic strength, either due to an increase of the concentration of the electrolyte or due to an increase on the valence of the present ions. The diffuse layer can move and can be considered a slipping or shear plane that separates the mobile fluid from the fluid that remains attached to the surface. The electric potential at this plane is the so-called electrokinetic potential or zeta potential (ζ). It measures the electrostatic potential at, or very near to the beginning of the diffuse layer and can be considered not be much different of the Stern potential.

Stability of Suspensions – DLVO Theory

Interaction between charged surfaces in suspension can be explained by the DLVO theory considering that the total potential of interaction between the surfaces of the particles is the sum of an attractive (V_A) potential, mainly due to van der Waals attraction forces, and a repulsive potential (V_R), dependent on several factors, such as temperature, double layer thickness (κ^{-1}) and Stern potential (ψ_δ)

$$V_T = V_A + V_R \quad (3)$$

The van de Waals attraction potential, V_A is given by

$$V_A = \frac{Aa}{12H} \quad (4)$$

where A is the Hamaker constant, a the particle radius and H the distance between particles.

The EDL repulsive potential, V_R , is

$$V_R = \frac{Be K_B^2 T^2 a_l^2}{z^2} \exp(-\kappa H) \quad (5)$$

where B is a constant and

$$\gamma = \frac{\exp\left(\frac{ze\psi_\delta}{2K_B T}\right) - 1}{\exp\left(\frac{ze\psi_\delta}{2K_B T}\right) + 1} \quad (6)$$

The total energy curve of interaction is depicted in Fig. 1.

DLVO theory allows defining the stability/instability conditions of a suspension: a stable suspension must have a high Stern potential and a thick double layer. Those conditions of stability are also related with the IEP value: the suspension will be stabilized for a pH value far away from the IEP and coagulated nearby to it.

Colloidal suspensions can be prepared in the dispersed, weakly flocculated or strongly flocculated states. In the dispersed state, the repulsive barrier (V_{max}) (Fig. 1) between the particles is higher than $K_B T$, the particles repel each other. In a weakly flocculated

Fig. 2 Interparticle energy interaction – Influence of the conditions of the medium. Reproduced from Balzer, B., Gauckler, L.J. 2003. Chapter 5.5 – Novel colloidal forming technique: Direct coagulation casting. In: Somiya, S., Aldinger, F., Claussen, N., *et al.* (Eds.), Handbook of Advanced Ceramics: Materials, Applications, Processing, and Properties. Volume 1: Materials Science. Academic Press; Elsevier Inc., pp. 435–458.

state, particles can aggregate in a low secondary minimum forming flocs in suspension at low volume fractions, or a particle network at higher volume fractions. In this case, there is an equilibrium separation distance between aggregated easy destroyed by stirring. On the contrary, when particles are aggregated into a deep primary minimum (V_A) the suspension will be strongly flocculated and for high solids loading slurries the particles will form a touching particle network. For more diluted suspensions individual clusters will be formed (Lewis, 2000). This explains the fact that, for a low solids loaded suspension, the coagulation process leads to non bridging particle aggregates and for high solids loading (higher than 50 vol% solids) coagulation leads to the formation of a continuous network without any macroscopic shrinkage.

As predicted by DLVO theory, in a stabilized suspension the repulsive interparticle forces are dominant. If they are eliminated, either by changing the pH of the medium towards the IEP or by an increasing of its ionic strength (Fig. 2(a) and (b)), the repulsive energy barrier ($K_B T$) decreases and the attractive forces between the particles will cause the high solids loading suspension to coagulate, forming a stable particle network that behaves like a viscoelastic solid (Balzer and Gauckler, 2003).

This is the main idea behind Direct Coagulation Casting (DCC), a ceramic green body forming process via colloidal suspensions, first developed and patented by Gauckler *et al.* (1999) to be analyzed in the following paragraphs.

Contrary to the slip casting process where the body is consolidated by removal of the liquid by the capillary forces through a porous mold, in DCC the green body is obtained by the coagulation process of the slurry casted in a non-porous mold. Accordingly, the green density closely corresponds to the solid loading of the starting slurry. Therefore, it is advantageous to use a solid loading as high as possible in order to control the final geometry, and to achieve higher dimensional tolerances by minimizing the possible distortion during drying and sintering shrinkage. On the other hand, the shaping of complex parts requires the slurry to fill easily molds of possible complex geometry, which means that the viscosity of the slurry has to be kept below some acceptable level in order to be poured and fill all the parts of the mold.

Direct Coagulation Casting (DCC)

Fundamentals of the method

As already referred, direct coagulation casting (DCC) process is based on the concept of the balance of repulsive and attractive forces between surface of charged particles.

A well stabilized aqueous ceramic suspension is cast into a non-porous mold and in-situ coagulation is carried out by shifting the repulsive force between the particles in the suspension to the attractive regime. This can be achieved via the control of the reaction rate of an organic reagent (the so-called substrate), already present in suspension. Decomposition products of the substrate can either shift the pH of the suspension towards the IEP or increase the ionic strength of the medium (compressing the EDL) both contributing to the destabilization of the suspension (Fig. 3). The internal reaction of the decomposition of the organic reagent may be either enzymatic catalyzed at room temperature (for example urea decomposition by urease) or thermally activated self-decomposing.

According to the range of stabilization of the suspension of the ceramic powder and to the value of its IEP, different organic reagents can be used to produce the coagulation of the suspension.

Examples are:

- A pH shift from acid to alkaline range can be obtained by: (1) enzymatic decomposition of urea catalyzed by urease (pH change from 4 to 9) or of amides by amidase; or (2) by thermally activated self-decomposition of urea, formamide, etc.
- For slurries stabilized in the alkaline range and with a lower IEP, a pH shift from alkaline to acid range obtained by: (1) enzymatic decomposition of glucose by glucose oxidase; or by (2) a thermally activated self decomposition of esters and lactones

Fig. 3 Coagulation of alumina suspensions by ionic strength increase (a); and by pH shift (b). Reproduced from Gauckler, L.J., Graule, T., Baader, F., 1999. Ceramic forming using enzyme catalyzed reactions. *Mater. Chem. Phys.* 61, 78–102.

- For example, the enzymatic hydrolysis of urea $\text{-CO(NH}_2\text{)}_2\text{-}$ catalyzed by urease in aqueous medium, leads to the formation of ammonia and carbon dioxide, and their reaction in water produces NH_4^+ and HCO_3^- and a small amount of CO_3^{2-} , with the buffer pH of the main products around 9. Those reactions will contribute to the destabilization of the aqueous suspensions by two effects: by a pH shift, until the value of the pH buffer and to an increase of the ionic strength due to the formation of ions (Balzer and Gauckler, 2003; Yu *et al.*, 2011).
- For example, alumina suspensions stabilized in the acid range, can be coagulated by the increase of the pH towards its IEP (around 9), due to the ammonia produced by the hydrolysis of urea. For powders with an IEP higher than 9, the suspension will be coagulated by an increase of the ionic strength.
- Urea can also be decomposed at $T > 75^\circ\text{C}$ allowing for a pH shift from acid to neutral and then, at the end, to alkaline, as ammonia is formed.

The strength of the wet shaped green bodies depends on the coagulation method used: it was found that flocculated bodies resulting from the coagulation of the slurry by pH shift has higher strength than those coagulated by ionic strength increase (Balzer and Gauckler, 2003). The result was justified by the short range hydration forces acting between the particles when the coagulation was done by increasing the salt concentration.

Although DCC has been successfully applied in the processing of oxide (alumina, zirconia) and non-oxide (silicon carbide, silicon nitride) (Gauckler *et al.*, 1999) there are some drawbacks of DCC that need to be eliminated (or minimized) (Xu *et al.*, 2016).

For example, coagulation of the suspensions by enzymatic hydrolysis of urea is an expensive process due to the high costs of the enzyme urease. Also, when the coagulation is due to an increase of ionic strength by monovalent ions a long coagulation time is needed. To avoid the use of the hydrolysis reaction catalyzed by enzymes the coagulation of the suspensions by thermally activated decomposition of organic reagents has been suggested (Santacruz and Binner, 2008). A new method based on the use of carboxylic acid derivatives, viz., lactones, as coagulants to obtain alumina bodies swiftly, without the addition of catalyzers in DCC process was proposed (Binner *et al.*, 2006b). In the next section the utilization of the thermal decomposition of carboxylic lactones will be analyzed.

Coagulation of suspensions by thermal decomposition of lactones

Hydrolysis of specific carboxylic-acid lactones allowed coagulation of concentrated ceramic slurries to the point that demolding of casted piece can be practiced without appreciable distortion (Binner and McDermott, 2006a). The increase of concentration of the weak C-acid decreases pH of the slurry to the point that it loses stability and moves towards the isoelectric point of the particles in suspension. Coagulation occurs when the balance of attraction of van der Waals forces between suspended particles and electrostatic repulsion of the molecules of dispersants adsorbed to their surface comes to the local minimum of potential energy between particles. There are specific advantages in using C-acid lactones as proton release source for direct coagulation casting (Binner and McDermott, 2006a; Studart *et al.*, 2002; Yin *et al.*, 2006). Coagulants are metal free organics. Water, ionic radicals in solution and active sites of solid surfaces act as nucleophiles to operate the additive hydrolysis reaction progressively turning the ring lactones into the corresponding conjugated acid. The time scales of reactions of hydrolysis of specific lactones and dissociation of the conjugated acids are of the order of minute or hours permitting addition of the C-acid lactones to stable slurries, degassing, casting into molds before the occurrence of coagulation. Detail descriptions of the ring-type molecular structure of C-acid lactones of 4-, 5-, 6- up to 9-membered rings can be found in the works of Binner and co-workers (Binner and McDermott, 2006a; Yin *et al.*, 2006). Stability of C-acid lactones to nucleophilic attack leading to hydrolysis may change by orders of magnitude depending of polar species in solution, ring coordination number, ring strain of cis and trans configuration and polar effect of added side radicals (Binner and McDermott, 2006a; Yin *et al.*, 2006).

The sequence reactions in DCC using C-acid lactones, as in the case of DCC of concentrated Al_2O_3 slurries with the 4-membered ring β -Butyrolactone (β -BAL), develops in three steps, the chemical reactions of hydrolysis of the β -BAL and

dissociation of the β -hydroxybutyric acid and the physical process of gelation of suspension (Yin *et al.*, 2006). In the temperature range 1–55°C the addition reaction of β -BAL hydrolysis in deionized water and in the Al_2O_3 slurry stabilized with ammonium polyacrylate exhibits first order kinetics with activation energy $Q_h = 59 \pm 5 \text{ kJ mol}^{-1}$, the corresponding time constant τ decreasing from $\tau = 270 \text{ min}$ at 25°C to less than half an hour, $\tau = 29 \text{ min}$ at 55 °C. The activation energy of the identical reaction in de-ionized water is higher, $Q_h = 87 \pm 5 \text{ kJ mol}^{-1}$, the reaction rate at 25°C being one order of magnitude slower than in the Al_2O_3 slurry. As hydrolysis proceeds by attack of a single nucleophile H_2O molecule, first-order is also displayed by the reaction mechanism of hydrolysis of most lactones (Yin *et al.*, 2006).

Henderson-Hasselbalch equation determines the proportion of weak carboxylic acid that dissociates and sets the value of pH of the solution, or slurry. Values of the dissociation constant of β -hydroxybutyric acid pK_a in de-ionized water at 25°C are in the range 4.68–4.82. For values of pH between 9.5 (stable Al_2O_3 slurries) and 6.5 (IEP of Al_2O_3), β -hydroxybutyric acid would be dissociated in pure water to more than five parts in one hundred (Yin *et al.*, 2006). Adsorption of β -hydroxybutyric acid on the surfaces of the slurry particles, complexation and forming of salts with surfactants hinders the dissociation of acid and decreases the effective values of pK_a in concentrated slurries. As in the Al_2O_3 slurries the hydrolysis of β -BAL yielding the β -hydroxybutyric acid is faster by approximately three orders of magnitude than the observed increase of H^+ ion concentration with time (Yin *et al.*, 2006). Phenomenological models that describe in quantitative ways the increasing of H^+ ion concentration, which determines the time for coagulation of concentrated slurries, necessarily differ from the observed kinetics of hydrolysis if the butyric acid lactones. The parabolic relationship for the change of pH with time, $\Delta\text{pH} = A(T,C)t^{1/2}$, was reported for dissociation of β -hydroxybutyric acid in concentrated Al_2O_3 slurries, the proportionality factor $A(T,C)$ increasing with temperature T (activation energy $Q_d \approx 89 \text{ kJ mol}^{-1}$) and initial concentration C of β -BAL (Binner and McDermott, 2006a; Yin *et al.*, 2006). In more general way good fitting to experimental results was found by applying the following power law of the $[\text{H}^+]$ ion concentration,

$$[\text{H}^+]^n = \left(K_0 e^{-\frac{Q_d}{RT}} \right) C^m t + [\text{H}^+]_0^n \quad (8)$$

with K_0 a constant, t time, n and m exponents of the power laws of time and of dependence lactone initial concentration, respectively, and Q_d the activation energy of the effective acid dissociation reaction. Integer order with $n = 1$, $m = 1$ was found from fitting Eq. (8) to the decrease in pH of 57.7 vol% castable Al_2O_3 slurry with $C = 1.6 \text{ wt\%}$ of glucuronic acid lactone (GrAL) as coagulant. Replacing the coagulant of same slurry for 0.5 wt% and 0.8 wt% of gluconic acid lactone (GAL) yields a fractional order with $n = 1.4$ and $m = 3.25$ (Studart *et al.*, 2002). Fitting of Eq. (8) to decrease of pH of concentrated Al_2O_3 slurries with D-gulonic- γ -lactone (D-GAL) at concentration of $2.5 \times 10^{-5} \text{ mol g}^{-1}$ yields $n = 2.2$ and $m = 1.4$ and $Q_d = 64 \text{ kJ mol}^{-1}$. This value is close to $Q_d = 68 \text{ kJ mol}^{-1}$ determined for the same system at 81 wt% solids (Binner and McDermott, 2006a). In analysis of the effect of C at 25°C in the same system exponents n and m present a dependence on C , decreasing from $n \approx m = 3.1$ at $0.52 \times 10^{-5} \text{ mol g}^{-1}$ to $n \approx m = 1.6$ at $5.3 \times 10^{-5} \text{ mol g}^{-1}$. From fitting of Eq. (8) to the same data one determines the following logarithmic decrease of pH with the concentration of D-GAL, at the fixed time $t = 5 \text{ h}$: $\text{pH} = -1.1 \ln(C) + 8.32$, with $C (10^{-5} \text{ mol g}^{-1})$. Eq. (8) is not adequate to describe the decrease of pH with time in concentrated Al_2O_3 slurries as a function of concentration of β -BAL at 25°C. An analogous logarithmic decrease of pH for this system was found, yielding for $t = 10 \text{ h}$, $\text{pH} = -1.28 \ln(C) + 8.78$, with $C (10^{-5} \text{ mol g}^{-1})$ (Yin *et al.*, 2006). Values of activation energy Q_d of coagulation rate constants for lactones span in a wide range of values from $Q_d = 61 \text{ kJ mol}^{-1}$ for D-glucono- γ -lactone to the $Q_d = 95 \text{ kJ mol}^{-1}$ and $Q_d = 96 \text{ kJ mol}^{-1}$ of γ -butyrolactone and ϵ -caprolactone, respectively (Binner and McDermott, 2006a). The effect of heating on acceleration of the processes and achieving short coagulation times by pH shifts closely follows the values of the activation energy (Binner *et al.*, 2006b; Yin *et al.*, 2006).

A summary of major effects and secondary factors that regulate reactions (I) of hydrolysis of CA-lactones, (II) of dissociation of carboxylic acids and (III) gelation of particle suspension is given in Table 1. Temperature, initial pH of the stable slurries,

Table 1 Dominant and secondary effects on the carboxylic acid lactone hydrolysis (I), carboxylic acid dissociation and slurry coagulation (III) reactions. (IEP – isoelectric point of solid surface, Ψ_δ – Stern potential $\sim$ zeta potential)

Reaction	I – lactone hydrolysis	II – acid dissociation	III – gelation
pH of suspension	High rates at high values of pH	pH limited	Converging to IEP
Lactone initial concentration	Rate of reaction (1st order kinetics)	Non-integer order, slow dissociation of weak acids from interaction with solid	Drying fracture for high contents. Ionic strength coagulation/rheofluidifying
Temperature of slurries	Thermally activation, $Q_h \approx 65\text{--}130 \text{ kJ mol}^{-1}$	Thermally activation, $Q_d \approx 60\text{--}100 \text{ kJ mol}^{-1}$	Thermal activation, $Q \approx \Psi_\delta$
Dispersant	–	OH^- neutralization	Desorption, IEP changes
Particle surface chemistry	Nucleophilic sites	Complexes	van der Waals binding strength
Impurities	Nucleophilic activity	Buffering	Heteroflocculation

concentration of CA-lactone, volume fraction of solids and composition and concentration of dispersants are major variables that control coagulation (Balzer and Gauckler, 2003; Binner and McDermott, 2006a; Gauckler *et al.*, 1999; Yin *et al.*, 2006). Reaction (III) gelation is mostly physical. Safe demolding of the piece requires a minimum threshold of yield strength of 6–10 kPa that makes the piece self-supported (Balzer and Gauckler, 2003; Binner *et al.*, 2006c). Mold removal becomes feasible when viscosity comes to 16 Pa s for shear rates in the range of 100 s^{-1} . This threshold corresponds to a pH shift from $\text{pH} \approx 9.5$ to approximately $\text{pH} = 7.5$ in gelation of concentrated Al_2O_3 slurries with solid fraction of 52–55 vol% (Binner *et al.*, 2006b; Yin *et al.*, 2006). The crossing point of dynamic storage (G') and loss (G'') moduli in small amplitude oscillatory rheometry allows a more precise definition of gelling time. It broadly corresponds to values of storage modulus $G' > 6 \text{ kPa}$ (Binner *et al.*, 2006b). DCC imposes conflicting requirements on solid volume fraction of the slurries. While one needs high solid loading to arrive to such high compressive strength in the gelled body, pouring and degassing of concentrated slurries require acceptably low viscosities of the slurry before coagulation. The low yield strength increases the probability of cracking during drying and slowed the acceptance of the DCC process by industry (Binner *et al.*, 2006c; Chen *et al.*, 2017; Gauckler *et al.*, 1999).

Convective heating to the isothermal temperature with protection of slurries from water evaporation and drying allows controlled gelling for values of gelling time above 1 h (Binner *et al.*, 2006c). The method was applied to prepare near-net shape pieces of Al_2O_3 ceramics in non-porous molds by DCC using D-gulonic- γ -lactone the slurries being heated to temperatures up to 80°C . Gelation of these slurries above 40°C is fast. Gelling time falls below the half hour and the volume inside may not reach isothermal conditions because of low thermal conductivity of slurries (Binner *et al.*, 2006c). Direct coagulation casting of white porcelain slips with 55 vol% solids is attainable with D-glucuronic-6,3-lactone (DGL) in concentrations of 2–3 wt% by heating the slips to 70°C and holding for approximately 15 min. The clay suspensions are stable at $\text{pH} \approx 7.5$. Fast hydrolysis of the DGL lactone at 70°C displaced the pH values of the porcelain slip towards $\text{pH} = 4.5$ (Mota, 2011).

Volume heating of the castable slurries with microwave energy allowed fast and homogenous heating in slip casting of sanitary ware (Das *et al.*, 2009). $\text{Al}_2\text{O}_3/\text{SiC}_n$ micro/nanocomposites of Al_2O_3 reinforced with nanoinclusions of SiC display high hardness and mechanical strength (Dong *et al.*, 2009). Large difference of isoelectric points of Al_2O_3 (IEP ≈ 9) and SiC (IEP < 3) would lead to heteroflocculation of concentrated slips during colloidal processing of $\text{Al}_2\text{O}_3/\text{SiC}_n$ composites. Addition of diammonium citrate to the slurry displaces the isoelectric point of modified Al_2O_3 surfaces to low pH values (IEP ≈ 3.5) and allow preparation of stabilized $\text{Al}_2\text{O}_3\text{-SiC}_n$ suspensions at $\text{pH} = 9$ with 5 wt% SiC_n and solid loading of 55 vol% to which D-glucurono-6,3-lactone (DGL) ($2.5 \times 10^{-5} \text{ mol g}^{-1}$) was added. Microwave heating of the concentrated slurry casted in plastic molds to 60°C and holding for 30 min accelerated hydrolysis of DGL lactone. The pH shifted from 9 to 6 and resulted in direct coagulation (Vieira, 2009). Time-dependent in situ hydrolysis/dissociation of DGL thermally activated by microwave energy promoted the coagulation of $\text{Al}_2\text{O}_3\text{-SiC}_n$ suspensions of high-volume fractions. Processed bodies presented high relative green density. Hydrolysis of DGL followed by the dissociation of the acid promotes coagulation in suspensions with solid volume fraction close to the critical packing.

Coagulation by high valence counter-ions (DCC-HVCI)

DCC by pH shift to IEP is a reliable process to produce ceramic bodies, but the wet strength might be not high enough for their handling. Shifting the interparticle forces from the repulsive to the attractive regime by increasing the monovalent ionic concentration through, for example the decomposition of urea catalyzed by urease, requires very high concentration of monovalent salt (2 mol L^{-1}) and the coagulation time became too long (Xu *et al.*, 2012a,b).

To overcome such limitations a modification of the DCC method, inducing the slurry coagulation by increasing the concentration of high-valence counter-ions was developed. The main idea behind the process is that the destabilizing power of an electrolyte is determined by the minimum concentration required to coagulate rapidly a suspension – the so-called critical coagulation concentration (CCC). DLVO theory is used to derive the expression that relates CCC with the counter-ion valence, z :

$$\text{CCC} = \frac{\text{constant}}{z^6} \quad (9)$$

Eq. (9) is the Schulze-Hardy rule, indicating that the minimum counter-ions concentration that will make the transition from a stabilized to coagulated slurry is inversely proportional to the sixth power of valence z . For $z = 1, 2$ and 3 the ratio of the CCCs are 1, 0.016 and 0.0014, respectively. As a consequence much lower concentrations of divalent and trivalent electrolytes needed to coagulate the suspension, comparing with larger concentration of monovalent electrolytes.

Results reported by the authors showed the potential application of high valence counter ions in colloidal forming (Xu *et al.*, 2012a). Based on this concept, a modification of DCC was proposed with a combination of the DLVO theory and the Schulze-Hardy rule, the so-called direct coagulation casting via controlled release of high valence counter ions (DCC-HVCI) (Chen *et al.*, 2017).

Although the process refers to the use of high valence counter-ions, all the reported work by the several authors had only employ divalent ions, mainly calcium Ca^{2+} and magnesium Mg^{2+} to increase the ionic strength of the medium, resulting in the compressing of the EDL of the surface particles and coagulation of the suspension. The method was applied to process alumina, zirconia (YSZ), silica and alumina-silica composites with calcium iodate, calcium citrate and calcium phosphate as the most common reagents to the release of Ca^{2+} ion. Concerning the release of Mg^{2+} magnesium citrate and magnesium oxide had been used. Besides the coagulation due to the increase of ionic strength, in some of the studies a thermally activated hydrolysis decomposition of an ester (Glycerol diacetate) was the other coagulation mechanism also to be present. Most of the studies found out that both coagulation mechanisms allow to obtain dense, homogeneous and high strength bodies in a short time (Xu *et al.*, 2015).

Alumina fiber-reinforced silica matrix composites with improved mechanical properties were prepared by this method (Xiao *et al.*, 2017) using the Ca^{2+} released by calcium iodate and the hydrolysis decomposition of glycerol diacetate (GDA) thermally activated at 70°C. Electrostatically stabilized suspension of silica with alumina fiber was coagulated by the release of Ca^{2+} ions from calcium iodate and also by pH shift due to the hydrolysis of GDA. This decomposition reaction occurs at high temperatures (70°C) forming acetic acid and glycerol. The acetic acid shifts the pH toward the IEP, promoting the coagulation of the suspension. Besides, with the increase in temperature the solubility of calcium iodate increases, releasing Ca^{2+} ions. Both mechanisms accelerate the coagulation of the suspension at high temperature (70°C). Processed bodies with homogeneous microstructure and good mechanical properties suggest that this colloidal method is promising to obtain ceramic-matrix composites with complex shapes, with uniform composition and high mechanical strength.

Calcium phosphate is another reagent that has been used for the release of Ca^{2+} ions to coagulate alumina suspensions stabilized in the acidic region with HCl (Xu *et al.*, 2012a). Calcium compounds formed in the alumina suspension release Ca^{2+} ions that will compress the EDL of the alumina particles and the suspension coagulates. Besides, the hydrolysis of hydrogenophosphate ionic species (HPO_4^{2-} and H_2PO_4^-) generates OH^- , which contributes to the pH shift to the IEP. The increase of the temperature of the suspensions will contribute to a rapid coagulation of the suspensions, due to faster release of Ca^{2+} ions.

The coagulation of alumina suspensions by the controlled release of Ca^{2+} from calcium citrate complex assisted by pH shift in the presence of glycerol diacetate has also been reported (Xu *et al.*, 2016). Alumina was added to a calcium citrate complex suspension obtained by mixing tri-ammonium citrate and calcium chloride. Afterwards the addition of glycerol diacetate (GDA) induced the coagulation of alumina in the chelated suspension, at different temperatures (40–70°C).

The release of Mg^{2+} ions from magnesium citrate and the pH shift in the presence of GDA has been also applied to the coagulation of stabilized Ytria-stabilized zirconia (YSZ) suspensions (Xu *et al.*, 2015). GDA hydrolysis reaction allows the decomposition of magnesium citrate, with the production of Mg^{2+} . Besides it will shift the pH of the YSZ suspensions and both those mechanisms will allow to process complex-shaped bodies.

Magnesium oxide (MgO) has been used by several authors as a coagulant agent. Alumina suspensions stabilized with ammonium poly (acrylate) (APA) were coagulated by MgO. Time-delayed in situ generated Mg^{2+} reacts with the dispersant, forming Mg-poly(acrylate), and shifting the adsorption equilibrium of the dispersant on the particles surface, with the consequent coagulation of the concentrated alumina suspension (Prabhakaran *et al.*, 2008, 2010). Fast coagulation with the increase in temperature by heating to 70°C may be due to an increase of the rate of reaction of MgO with the molecules of the dispersant, due to an increase in solubility of MgO and concentrating Mg^{2+} ions. These results were recently corroborated by other authors (Nair *et al.*, 2019) who performed similar studies.

The strength of wet-coagulated samples prepared by DCC-HVCI was found to be higher than that prepared by increasing monovalent electrolytes (urea). The coagulation mechanism of DCC-HVCI is the compression of electrical double layer by the high valence counter ions that lead to the close contact of suspended particles. During the process the aggregation of particles results in the shrinkage of the suspension and loss of water. The shrinkage rate decreases with increase in coagulation temperature which is similar to the effect observed in compressive strength. Large shrinkage rates mean strong aggregation of particles and water is squeezed out of the sample which leads to high green density and contributes to high compressive strength. Also, cracks are easy generated at high temperature and are detrimental to the mechanical properties of the green body. The increase of strength of dry samples with calcium iodate concentration may be due to the slow decomposition of excessive calcium iodate during drying processing.

Advantages and Limitations of DCC

In CICECO laboratory, high density ($\approx 60\%–80\%$) (MgAl_2O_4) green bodies were prepared by colloidal casting methods (slip casting (SC), DCC and Centrifugal Casting (CC)). (Curveira, 2008). Electrostatically stabilized aqueous suspensions with solids content varying between 50 and 65 vol% were prepared to produce samples by the three different casting techniques. Enzymatic decomposition of urea catalyzed by urease at room temperature was used in the direct coagulation casting via pH modification. Compressive strength measurements were performed on cylindrical samples of wet coagulated bodies with different enzyme concentration and coagulation time. Results of relative density after sintering showed that higher particle packing is promoted by DCC (relative density around 88%) and by centrifugal casting (around 97%), when comparing with slip casting (75%). Although nearly full densified samples were achieved by CC, differential settling is observed, creating density gradients along the bodies.

DCC was also applied in our laboratory in the study of the consolidation process of a porcelain slurry stable at pH ≈ 7.5 , promoted by the thermal activated self decomposition of D-glucorono-6,3-lactone (DGL) (Mota, 2011). The coagulation rate of processed bodies depends on slurry solid loading, temperature and DGL concentration. The results revealed that the thermal decomposition of DGL decreases the pH of the medium. A kinetic model based on a first order hydrolysis and dissociation reactions can describe the pH changes inside slurry due to the DGL thermal decomposition.

Conclusions

Basic concepts behind the DCC processing, and the developments introduced to improve the properties of the processed bodies are reviewed.

Direct Coagulation Casting (DCC) is an advanced ceramic powder compact forming process that has demonstrated the capability for fabricating complex near-net shapes. It is potentially advantageous to process dense, homogeneous bodies at low costs. In this paper the basic concepts behind this technique have been discussed, as well as the developments introduced. The coagulation of high concentrated stabilized slurries by the decomposition products of thermally activated hydrolysis of carboxylic acids have been analyzed in detail, with the interpretation of the factors influencing the hydrolysis reaction rate and weak acid dissociation.

Based on the combination of DLVO theory and Schulze-Hardy rule the coagulation of high solids stabilized slurries by divalent ions controlled release in the slurry, was also investigated.

DCC has been applied to a variety of ceramic materials (advanced as well to conventional clay-based). Comparing to slip casting the application of DCC to the processing of the same type of material has proved to produce bodies of better properties.

Although all of the potential advantages of this colloidal technique, as far as to the present knowledge of the authors, commercial applications have been initiated only for smaller productions of small pieces. For industrial applications there are still some drawbacks ought to be removed.

Extrusion

Stuart Blackburn and Marcin Szymiczek, University of Birmingham, Birmingham, United Kingdom

Extrusion

Extrusion is a process where a material undergoes plastic deformation by the application of a force causing that material to flow through an orifice or die. The material adopts the cross-sectional profile of the die and if the material has suitable properties, that shape is retained in the final extrudate. The force required for this process is normally achieved by either a moving piston or rotating auger in a barrel. In the latter case the process is continuous and discrete parts are created by cutting the extrudate into pieces of a predefined length.

Extrusion of ceramic materials can be traced back to 1643 with the manufacture clay bodies and with commercialization being first reported for brick manufacture at the turn of the 19th century, [Reh \(2007\)](#). In terms of manufacturing volume and mass, clay based building products still account for the vast majority of items made by this shaping method today. Almost any ceramic material can be extruded if the process gives the required shape. Thus, ceramics extrusion is in principle a simple process, at least in concept. There are three key aspects to the process: a machine is required to generate the pressure (the extruder, piston or screw), a die is required to shape the material and a formulation is needed to render the ceramic powder or precursor plastically deformable.

The Extrusion Process and Material Examples

Pressure Generation

Piston extrusion

Piston or ram extrusion, where force is directly transferred to the paste or plastic body by movement of a piston within a barrel, is the simplest of approaches to generate the required pressure for extrusion ([Fig. 1](#)). Ram extruders are batch machines however, with appropriate feed systems; they can be refilled to give a cyclic but automated extrusion process. The piston or ram may be driven mechanically by lead screws or by hydraulics. Degassing the paste feed can be an issue in these machines, but a vacuum can be applied or air forced from the system by holding the paste under pressure in the barrel prior to extrusion. Ram extruders are able to generate pressure independently of the material properties giving them a key advantage over auger systems for some materials. As a result of this feature and their simple geometric movement, they are useful for precise work and material characterization.

Auger/screw extrusion

In screw extruders, the plastic body is transported by a screw configuration and the interaction between the material, the screw, and the barrel wall, cause the material to be conveyed and to develop pressure ([Burbidge and Bridgwater, 1995](#); [Botten et al., 2003](#)).

Fig. 1 A schematic of the extrusion methods, (a) ram extrusion, (b) single screw extrusion (c) twin screw extrusion (here co-rotating and intermeshing) and (d) roll extrusion. P is Pressure.

Thus, the amount of pressure generated is a combination of the material formulation, the geometry of the extruder and the pressure drop developed by the die. This means that not all materials can be extruded from certain designs of screw extruder however, when they work the major advantage of screw extruders is that they produce continuous extrudate.

There are two common forms of screw extruder, machines with single or twin augers. Single screw extruders are the most common and frequently found in the extrusion of clay bodies. They are often two-stage machines where the first auger compacts the material and passes it through a perforated plate into a vacuum chamber where the paste strands are degassed. A second screw/auger then re-compresses the paste and generates the pressure required to extrude the material through the chosen die. Mixing in single screws is limited, because the flow is plug-like within the screw channel between the flights. Twin screw extruders come in many forms and the screws may be co- or counter-rotating and non-intermeshing or intermeshing. Intermeshing co-rotating twin screws are capable of generating pressure where other systems would fail to do so. This is due to them being able to develop positive pressure if the screws are configured appropriately. They can, by the appropriate selection of the screw and kneading elements, be used to mix the formulation into a paste before extruding it. This combined mixing and extrusion is perhaps most commonly practiced in catalyst manufacture.

In other extrusion systems, for example, in the field of catalyst manufacture, it is possible to generate pressure by roll extrusion where the paste is squeezed into the nip of two counter-rotating perforated rolls ([Fig. 1](#)). This allows the manufacture of short extrudate sections at extremely high throughput rates.

The Die

The main function of the die is to create the required cross-sectional shape and generate a pressure drop. The entrance can be shaped to ease flow and reduce or eliminate dead-zone formation. [Patel et al. \(2007\)](#) shows that a well profiled entry can reduce defects and phase migration (see later sections). Anything more complicated than a simple solid rod will require the die to have cores in place (sometimes called mandrels) and they will need to be supported by bridges (sometimes called spiders). This is true for the simplest tube to the most complex honeycomb designs.

Paste Formulation

Manufacturing cycle

When considering manufacture by extrusion it is important not to think only of the extrusion process itself but also of the full process cycle, which includes: solid particle preparation and conveying, dry mixing, wet mixing, pugging (kneading), degassing, die extrusion, extrudate (exiting material) handling, cutting; drying and firing/calcining. For brevity in this review, we consider only aspects which specifically influence the extrusion process. The reader is referred to other works such as [Onoda and Hench \(1978\)](#), [Funk and Dinger \(1994a\)](#) and [Rahaman \(2017a\)](#) for a broader description.

Requirements

Before delving into how to design and make a paste it is worth stating what properties are important in extrusion. For processing, a ceramic paste should be:

- *Shear thinning*: This property is almost always encountered in pastes if an appropriate particle packing and solids loading are used. During processing material undergoes a transition from highly “viscous” to less ‘viscous’ meaning that pressure does not rise monotonically with increasing extrusion speed. After extrusion the paste should recover its initial high “viscosity” (*viscosity used here to define consistency, not a measured value*) almost instantaneously. Further the paste may exhibit an apparent yield which, again if recovered rapidly, is an advantage for shape retention. Should the material exhibit slow recovery of the original properties (thixotropy), this can lead to problems with handling after extrusion.
- *Slip at the wall*: [Benbow and Bridgwater \(1993\)](#) indicate that because a fluid maldistribution develops at the interface between the paste and the extruder wall, that slip occurs. Wall slip can be exploited to ease extrusion and reduce wear, for example by:
 - Introducing fluids at the wall
 - Inducing fluid migration to the walls

However, it can also be detrimental, as it can prevent the forward conveying of the paste in a single screw extruder or in extreme cases cause the extrusion process to fail as the pressure drop in the system increases through fluid drainage.

- *Stable under a range of shear conditions*: In a good formulation the pressure should not change with time as the extrusion process continues (i.e., reasonably large processing window). The components of the paste should remain uniformly mixed without phase separation (no gross liquid maldistribution).
- *Stable after extrusion*: In essence the paste should have a sufficiently high yield stress or apparent viscosity to not slump under its own weight, [Benbow and Bridgwater \(1993\)](#).

These aspects are of course desirable but in formulating a paste the properties of the final product must be considered and so frequently a compromise is required between what is necessary for optimal extrusion and product performance.

Fig. 2 Some important factors which influence the behavior of pastes.

Basic formulation

Paste formulations comprise two main components: the ceramic precursor powder and binding liquid. The simplest of all systems would be a clay water suspension where the interaction between the clay particles and the water are sufficient to impart the required plasticity. However, for most materials, they require some further additions to render the mix plastic. Some factors which influence the characteristics of a paste are summarized in [Fig. 2](#).

Particle packing

If the liquid phase is fixed in composition then for any given powder volume addition it is particle packing that imparts the greatest rheological change to the paste. Many studies on particle packing refer to the packing density, which describes the ratio of the volume of solids (particles) to the total volume of the arrangement (particles with voids between them). In random packing, the packing fraction is typically 0.635–0.640 for mono-sized spheres but it is probable that in real systems with interactions between the particles this value falls to 0.57–0.61 and is termed loose random packing, [Rahaman \(2017c\)](#). In this arrangement the particles would be in direct contact and as a consequence the frictional forces would be high if the mass was sheared with a liquid volume sufficient to fill just the voids. [Blackburn and Wilson \(2008\)](#) indicate that in conventional extruded products an excess of 2–5 vol% of the binding liquid is typically added to allow flow. This will decrease the solids loading of the extrudate slightly.

The remarks on solid-liquid ratio hold true even when the particle packing density is increased. In practice packing density can be increased by using wider particle size distributions and typically bi- or tri-modal particle size distributions are used to illustrate this behavior. As smaller particles fill the voids between the larger ones, less binding liquid will be required to fill the interparticle voids and to have the same free fluid to allow flow. Increasing the packing density of the solid phase has several advantages:

- The body will have higher green density on drying. With less binder to remove defects can be reduced to give denser bodies.
- Phase migration (paste stability in flow) will be reduced as the free path for the separation mechanism is reduced.
- The same rheological character can be achieved by reducing the liquid content. Alternatively for the same liquid phase content the flow at the same velocity will require commensurately less force.

A number of equations have been derived to predict the relationship between the relative viscosity and the incorporated solids loading as described by [Rutgers \(1962\)](#). Nevertheless, the majority of them are derived for hard spheres; any colloidal, electrostatic or steric interactions are not included and thus a divergence from the experimental plots has been observed, especially for high solids loading as described by [Mew and Wagner \(2012a\)](#). Some of the popular relationships for hard spheres that the reader may encounter are the Krieger-Dougherty and Chong equations, the former described in [Blackburn and Wilson \(2008\)](#). These equations

do not offer an explanation for shear thinning behavior of pastes as they only consider viscosity; the changes in voidage brought about by flow of non-spherical powders as they align are not incorporated either.

Particle packing is clearly influenced by particle shape. A perfect spherical morphology is assumed in most of the calculations and the real packing density with irregular particle shapes is lower than the spherical prediction (see sphericity or relative roundness and particle roughness in [Rahaman \(2017c\)](#) and [Shinohara \(1997\)](#)). A more dense packing could be realized by mixing different morphologies of significantly different size, [Rahaman \(2017c\)](#), [Blackburn and Wilson \(2008\)](#), [Shinohara \(1997\)](#), [Brouwers \(2006\)](#), [German \(1989\)](#) and [Blackburn and Böhm \(1994\)](#). One of the simplest ways to mitigate high viscosity during processing is to use powders with wide particle size distribution and obtain a homogenous distribution of particles throughout the specimen (which might be detrimental to sintering). This is discussed further in the following section.

Designing paste formulations

The final formulation of the paste will require accurate control of the liquid content as small variations can significantly affect the flow characteristics. For pastes formulated directly to the final composition, the proportion of binder must be determined. An estimate of the required liquid volume can be established by the so called Water Adsorption Test (WAT). A small amount of powder (2–4 g) can be mixed manually with predefined amounts of demineralized water numerous times. Formation of a paste-like mass is assessed by visual and physical inspection. With this approximate water content a larger mass can be prepared generally reducing the number of trials to reach the required consistency. Preparation of pastes with different liquid contents allows a plot of a reciprocal of pressure for a given ram speed against a ratio of the binding liquid to the powder to be constructed. Through extrapolation to the solids loading axis – indicating an infinite pressure – the minimal required liquid content can be identified, this approach is described by [Blackburn and Wilson \(2008\)](#), [Clemens et al. \(2007\)](#) and [Blackburn and Böhm \(1994\)](#). It is commented on by [Benbow et al. \(1987\)](#) and [Blackburn and Böhm \(1993\)](#) that this extrapolation shows an approximate linear relationship in this setting but the reasons behind this behavior are not yet fully explained.

Particle size distribution – Adjustment by modeling

The particle size distribution can be adjusted to lower the paste viscosity. There are some competing aspects to consider in any discussion of mixing particles of different size. There will be reducing returns as more distributions are combined in terms of increasing packing density and thus reducing viscosity for a given liquid content, each particle in the system would need to be placed in an ideally shaped void to achieve substantial improvement, [Shinohara \(1997\)](#) and [Rahaman \(2017c\)](#). Furthermore, although the density of the resultant green body will increase this may not be an advantage to the final sintered product as it may promote, for example, abnormal grain growth and/or not give the required microstructure. Of course these statements are very general and each product will have its own issues. [German \(1989\)](#) and [Brouwers \(2006\)](#) state that bi- or tri-modal size distributions should contain particles that differ in size by at least 7 times between each neighboring modality to give optimum results. The ratio between two different sized powders is termed R . This minimum size difference value comes from the requirement for the particles to sit discreetly in the structure such that the smaller fraction does not affect the packing of the larger one. This concept was first described in the works of Furnas (citation of Furnas' works available in [Brouwers \(2006\)](#)). Equations to calculate bimodal packing density and the remaining porosity with this assumption yield:

$$f_2 = f_1 + (1 - f_1)f_1 \quad (1)$$

$$\Phi_2 = 1 - f_2 = (1 - f_1)^2 = \Phi_1^2 \quad (2)$$

where f_1 and f_2 are the packing densities of the mono-sized and bimodal mixture, respectively, and Φ_1 , Φ_2 are the interstitial pore fractions for the respective packing densities. An example of this calculation is provided by [Rahaman \(2017c\)](#). Here it is worth pointing out the apparent increase in the packing density as the ratio of the size of large particles to small particles tends to infinity. The aforementioned assumption of non-disturbance holds with the minimum ratio values of 7–10. There are modifications which provide solutions when the particles interact, where the smaller particles influence the effective volume, and therefore the packing density, of the larger particles. For this reason [Karlsson and Spring \(1970\)](#) modified their initial approach and accounted for the change in the volume for bimodal mixtures, when even a miniscule inclusion of the finer particles causes an expansion. [Blackburn and Böhm \(1993,1994\)](#) demonstrate good agreement in pastes containing alumina and alumina with glass fibers when applying these principles.

In most real situations changing the particle packing comes from mixing continuous size distributions, as discrete monodispersed fractions are rarely encountered. This is reflected in the models created to calculate idealized distributions. One of the most popular approaches to calculating ideal particle size distributions stems from the Andreassen equation, [Andreassen and Andersen \(1930\)](#), [Rahaman \(2017c\)](#) and [Sutcu and Akkurt \(2007\)](#), modified by [Funk and Dinger \(1994a\)](#):

$$F_M(D) = \frac{D^n - D_S^n}{D_L^n - D_S^n} \quad (3)$$

where $F_M(D)$ is the cumulative mass fraction of particles finer than a size D (also called cumulative volume percentage finer – CVPF), D_L is the largest particle size in the distribution, n is an empirical constant (fitted numerically) and D_S is the minimum particle size in the distribution. The n exponent that is fitted to the equation has no physical explanation and derivations such as one presented by [Zheng et al. \(1990\)](#) have attempted to mitigate the issue. This approach led to defining n as:

$$n = -\log \Phi / \log R \quad (4)$$

Fig. 3 The exponent n calculated for different values of interstitial pore fraction ϕ and size ratios R . The lower the pore fraction (the higher the packing density), the greater the differences between each size ratio (n value).

where Φ is the interstitial pore fraction and R the size ratio for the packing of the system. The original work by Andreasen predicted values of n between 0.3 and 0.5 whereas 0.37 was predicted by the Dinger-Funk particle size distribution, [Zheng et al. \(1990\)](#). n has lower values with the increasing size of particles due to larger pore fraction present between them. What directly follows is that the calculations of CVPF (Eq. (3)) indicate larger amounts of finer particles are needed for optimal packing. As shown by [Yu et al. \(1997\)](#) the evaluation of the exponent value from the Dinger and Funk equation can differ for non-idealized situations. In their study the lowest porosity was shown to be for $n > 1$. The discrepancy when compared with the previous works is ascribed to the agglomerates forming in the mix; models like the one presented by [Yu et al. \(1996, 1997\)](#) consider more realistic descriptions of empirical examples. The aforementioned minimum size ratio of 7–10 between particles can be easily justified by drawing a graph for each given size ratio R : the calculated values of n plotted against the assumed voids volume or packing density. Starting from $R = 7$ the differences between higher size ratios with regard to the value of the exponent n at the same values of void ratios start to disappear, as shown by [Fig. 3](#). In practice, the model described by [Funk and Dinger \(1994a\)](#), yields the optimum particle size distribution for a given particle size range and packing density.

In conclusion the packing density might seem to constitute a good basis for high quality components predictions and to a large extent it does. Unfortunately the second important factor is the uniformity of the particle spatial distribution – changes in the fractional density across the specimen. [Burk and Apte \(1987\)](#) show that with wide distributions, there is a higher degree of inhomogeneity in terms of density that scales proportionally with the width of the particle size distribution. [German \(1989\)](#) states that most of the models do not account for this aspect. This phenomenon may pose a significant issue during sintering when the densification can cause significant differential strains in the component. The solution requires good and efficient mixing.

Mixing

Mixing plays an important role in paste formulation. While extrusion can create its own defect forms (Section “Extrusion Defects”), if the feed itself is not properly homogenized, then mixing defects will arise which can significantly influence the final properties of the ceramic. There are essentially two main routes to preparing extrudable highly loaded suspensions: the first is preparation from a suspension with lower solids loading by either removal of the fluid phase to the required paste liquid concentration, phase

change or induced rheological change and the second is preparation by forcing the ingredients to mix at the required concentration.

Any ceramic system of interest can be dispersed using colloidal chemistry techniques in combination with a mixing system (often ball milling or some form of a stirred tank) to generate a low viscosity, agglomerate free suspension. With clay based systems such as porcelains for insulators, the suspension or slip can then be dewatered by filtration. The filter cake which is produced can be sufficiently plastic to allow extrusion if the liquid phase content is controlled. The method has also found favor in high purity ceramic extrusion where ultra-clean sols are conditioned, gelled and dewatered to give an extrudable paste. When pushed to the limits of practical processing high strengths are attained. For example zirconia-toughened alumina extrudates with strengths in excess of 1.2 GPa have been reported by *Kaya and Butler (2003)*. This technology is also used to make high surface area γ -alumina catalyst supports, *Winstone (2011)*. Even in these systems mechanical mixing is required and here the body of literature developed in colloid and chemical engineering science can be useful in designing an efficient and defect limiting production line. There have been a number of papers which have essentially used elements of the direct coagulation casting process (*Graule et al., 1996; Baader et al., 1996; Gauckler et al., 1999*) to develop paste materials. In these a highly concentrated but dispersed suspension is formed and the paste is developed by either changing the pH or the electrolyte concentration. By way of example *Davies and Binner (2000)* produced alumina slurries at around 50 vol% with ammonium polyacrylate and then coagulated the system using ammonium chloride. *Pagnoux et al. (2006)* used a commercial anionic polyelectrolyte with sulfonate and carboxylate functionalities to stabilize an alumina powder and then a cationic polymer (chitosan) to complex with the ionic stabilizer to coagulate the system in situ, followed by extrusion.

For many applications the system may separate on filtration leading to performance issues. Thus it is common to mix the formulation ingredients directly to the final formulation. The order in which the various components are added as mixing continues is perhaps a matter of preference and/or practice. For example should the powder be added to the liquid or the liquid to the powder? It is possible to make the binder system and add that liquid to the insoluble particles or add the particles to the binder system. Generally, in the authors' experience the former is more successful at dispersing agglomerates as the initial material is rather stiff. One should think of it like making a roux in the preparation of a white sauce, there is a good reason why this has been practiced by chefs; it stops the paste being lumpy. Alternatively all the dry ingredients, including some of the solid binder phases which are subsequently solubilized, can be pre-mixed and then the solvent added. When taking these approaches the mixer needs to be rather robust, Z-blade and planetary mixers are used as well as calendar rolls. Generally, they all have high levels of material deformation but the rate at which that deformation is applied, be it elongation or shear, is relatively slow, such that shear rate might be described as moderate. The greater the degree of shear or elongational strain applied the better in most cases, though some materials can be sensitive to this aspect (catalysts for example). It can be shown that elongation is better than shear at mixing pastes and the reasons for this are demonstrated mathematically by *Cogswell (1981)*. A comparative table of mixers for plastic forming (kneaders) is presented by *Takahashi (2006)*, where classifying factors such as particle size, viscosity, power and kneading capabilities are used.

There are two main aspects to mixing that should be considered: (1) how well does the system disperse the ingredients (breakdown the agglomerates and generate homogenous system on a micro-scale) and (2) how well does the system ensure uniformity throughout the mixed body, known as distributive mixing. Ram extrusion and single screw extrusion are not good distributive mixers due to them running predominantly in laminar and plug flow. Dispersive mixing will of course occur as the material is forced from the barrel through the much smaller die, *Böhm and Blackburn (1994a,b)* and *Wildman and Blackburn (1998)*. Co-rotating intermeshing twin screw extruders can be used as very effective paste mixers because they can have kneading and hold up elements incorporated in the screw design. Twin screw extrusion where the mixing is undertaken penecontemporaneously to extrusion is not commonly practiced in general ceramics but has found application in catalyst support manufacture. The mixing performance of these systems has been evaluated by a number of workers and it has been shown that highly efficient mixing is possible if the flight geometry and hold up are optimized, see for example, *Edirisinghe and Evans (1986)*, *Diemer et al. (2011)*, *Wei et al. (2014)*, *McGuire et al. (2007)* and *Onoda and Hench (1978)*.

Paste additives

As mentioned in Section "Basic formulation" the plasticity of pastes prepared with powders other than clays can pose significant problems. A major issue is liquid phase migration which if extreme can lead to equipment damage due to a rapid and sudden increase in pressure. To prevent such issues and improve the overall paste-like, plastic behavior, a number of additive types are commonly incorporated and these include binders, surfactants, plasticizers and lubricants (*Hölzgen and Quirmbach, 2007; Onoda and Hench, 1978*). The function of these is described in the following paragraphs:

- *Binders (thickeners)* are added to improve the coherence of the paste usually by increasing its yield stress. They influence the rheology of the binding liquid by raising its viscosity, preferably transforming it into a shear thinning fluid, *Onoda (1978)*. Generally, a shear thinning liquid aids flow at higher extrusion rates and helps retain shape in the final extrudate. However, *Collomb et al. (2004)* show that care must be taken when imparting such behavior as liquid phase migration may increase to a significant level when the shear thinning exponent is too low. The fluid consistency, κ_s (see *Eq. (6)*), also plays a role and can decrease the process speed value at which phase migration occurs, acting to counter the shear thinning advantage or possible disadvantage.

The choice of the binder is related to the type of imparted stabilization at the particle level (electrostatic, steric or electrosteric) and compatibility with a given paste system, when both the molecular and final product properties are considered. A simple guide

for binder selection is to consider the following aspects: solubility of the binder, its burnout behavior, compatibility with other additives (e.g., dispersants) and its rheological behavior (the shear rate, temperature and – in undesirable cases – time dependence). To simplify the selection even further, it is possible to classify the binders according to their viscosity by arbitrarily assigning viscosity levels for grading, based on the concentration equivalent required of each grade to substitute the other. With categorized binders it is possible to calculate the binder content with Eq. (5):

$$b = \left(\frac{100 - f}{f} \right) \left(\frac{\rho_L}{\rho_B} \right) \frac{\gamma \log \mu}{100(V_B/V_S)} \quad (5)$$

where b is the parameter describing the viscosity grade of a binder, f is the packing density of the powder, ρ_L the density of the liquid, ρ_B the density of the dry binder, γ – liquid saturation of the voids (ratio of the liquid used and voids volume), μ – the dynamic binder viscosity (~ 100 Pa s for extrusion, Onoda (1978)), V_B and V_S are binder and solid volumes, respectively. The fundamentals and examples of this methodology are given by Onoda (1978) and a modern description of organic binders is given by Rahaman (2017b).

Examples of common binders include: methyl cellulose (and many other cellulose derivatives such as hydroxypropyl methylcellulose), bentonite (clay), polyethylene glycol, boehmite peptised with nitric acid, ammonium polyacrylate, polyvinyl alcohol, glycerin and guar gum (Blackburn and Wilson, 2008; Onoda, 1978; Rahaman, 2017b). There are many others gums and resins that exhibit similar behavior. Many binders could be used for the same core powder as evidenced in the review by Blackburn and Wilson (2008) but their compatibility in the final component (in a commercial setting) may be quite different from the processing compatibility.

- *Surfactants* are compounds that affect interfacial interactions between particles and liquids. The resultant wetting by the liquid is increased and may cause changes in the total amount of liquid required to impart plasticity. Surfactants tend to be compounds with hydrophobic and hydrophilic ends (Hölzgen and Quirnbach, 2007).
- *Plasticizers* are materials that have the ability to decrease the yield stress by preventing the binder from creating bonds; the result is increased flexibility (a softer binder). Examples include glycerin, polyethylene glycol, polypropylene glycol and propylene glycol (Onoda, 1978).
- *Lubricants* are classified according to the type of lubrication they provide: this may be internal between the particles or external, with regard to interaction with the containing surfaces. Lubricants decrease the overall pressure by aiding materials sliding. Examples include fatty acids and polyethers (Hölzgen and Quirnbach, 2007).

It should be noted here that there is an emerging field of particulate suspensions with relatively low solids loading of 15–45 vol%, where the formulations are enhanced by secondary immiscible liquid additions with either better or worse wetting capabilities than the main liquid. A number of workers have investigated the possible implications of this including Koos and Willenbacher (2011), Schneider *et al.* (2017) and Danov *et al.* (2018). In the most recent study by Weiß *et al.* (2019) this technique was tested by extruding such formulations with a twin screw extruder. Although the apparent yield stress increase achieved with these compositions may provide enough plasticity for the extrusion process, it is somewhat doubtful that it would be sufficient for the post-extrusion handling (see the yield stress description in the next section).

Characterization of Paste Formulations

General Characterization

Physically extrudable pastes lie in narrow region of the possible liquid solid ratios that can be formulated. They are concentrated suspensions in which the solids loading in combination with the interactions between the particles and the fluid lead to the material exhibiting an apparent yield stress yet exhibit the ability to flow without excessive damage to the equipment being used. The consequence of this is that these materials require some thought in terms of how to quantify their behavior. The materials exhibit some aspects of solid behavior and some of fluid. Conventionally the tests for the material's suitability for extrusion have focused on simple physical tests and on the determination of plasticity. There are a number of tests for plasticity such as indentation, primarily used to determine yield (Benbow and Bridgwater, 1993), torsion (Chandler *et al.*, 2002; Vandeneede *et al.*, 1997) and unconfined compression (Norton, 1970). They generally apply a load either statically or sinusoidally and measure the deformation of the body. The values quoted tend to be specific to the test. A common index is workability which is measured during the axial compression of a billet, defining the maximum stress before failure or fracture occurs, as described by Norton (1970). The complexity of measuring the flow has been highlighted by Chandler *et al.* (2002) in discussing the constitutive laws and the common tests employed to measure paste materials. In order to determine the true constitutive behavior, techniques such as confined triaxial testing, can be applied and these have been shown to be useful in developing computer simulations. Most of these methods could be considered to measure small deformation increments and extending them to large scale deformation can be undertaken through computer simulation (Patel *et al.*, 2017). They can yield interesting data on the structural development during the extrusion process but are generally computationally intensive (Patel *et al.*, 2007).

As a consequence of some of the limitations encountered in using the methods outlined above it is logical to evaluate the material in the extrusion environment. Capillary rheometry (ram extrusion) clearly represents the process of extrusion closely but it does have its limitations as the boundary conditions are not necessarily known, Gleißle and Graczyk (2007), ASTM International (2017). In these experiments, pressure is recorded as a function of flow rate for a given die of circular cross-section. Several such

Fig. 4 Flow behavior of pastes: (a) schematic of plug flow in a ram extruder, (b) paste flow profiles without wall slip and the telescoping profile which may develop in the flow of non-uniform bodies, (c) the flow behavior based on solids concentration and the expected pressure and velocity profile in the barrel and die regions of a ram extruder. 0.7, 0.8 and 0.9 are the shear thinning indexes for the shear thinning region only; possible shear thickening region after critical shear rate. tests with barrels and dies of different diameters (and lengths for the latter) give a succinct description of the behavior of the bulk material. The underlying assumptions of the technique are:

- The paste is incompressible,
- The paste is homogeneous and unchanging with time,
- Laminar and steady flow is developed,
- That at the wall there is either no slip (conventional liquid assumption) or pure slip (conventional plastic assumption).

All of these assumptions are subjects of debate as practical tests have shown high variability and interpretation can be challenging. The following discussion considers some issues that arise when examining capillary data and Fig. 4 gives a pictorial aid to the concepts being described.

Yield stress

Zheng *et al.* (1992) states that depending on the definition, yield stress can be identified as the stress at which flow starts. In capillary flow this can be identified by extrapolation of the flow data to zero flow rate or shear stress depending on the adopted approach. It is important to note that usually the assumption of uniformity fails and the measured yield stress values are different in different tests even when the tests are scaled with constant part dimensions ratios (barrel to capillary diameter ratio and capillary length to its diameter ratio), Khan *et al.* (2001) and Bryan *et al.* (2017). The existence of a yield stress is not argued for or against here but due to the wide acceptance of its applicability in the engineering field of extrusion, with materials being characterized more commonly on a macro-, rather than a micro-scale, it is included. It is interesting to note that when the data is fitted by using curve fitting routines it is common to find no yield stress but an extremely strong power law relationship. The reader is referred to works that discuss this property at length: Zheng *et al.* (1992), Barnes and Walters (1985), Coussot (2014) and Barnes and Nguyen (2001). For engineering purposes, the value of the yield stress for ceramic pastes should be equal to a certain minimum required to retain shape after extrusion. Some authors like Toutou *et al.* (2005) and Khelifi *et al.* (2013) cite 0.02 MPa, others like Blackburn and Böhm (1994) indicate 0.2 MPa. These differences stem from the requirements of the applications being considered. Here it is recommended taking both the geometric complexity and overall size of the final component into account. Shapes like solid rods can be close to the lower boundary, whereas hollow tubes and catalysts with flow channels will need to be close or higher than the latter value. The maximum is dictated by the lack of lubrication at the die wall – this is easily distinguished by strong discoloration present on the extrudate after extrusion. According to Blackburn and Böhm (1994) this occurs when the paste yield is above 2 MPa.

Liquid phase migration

Liquid Phase Migration or Liquid Phase Maldistribution (LPM) is the separation of the binding liquid from particles under an applied pressure and the flow experienced in extrusion. The assembly of particles may be thought of as a filter bed (moving slowly) through which the liquid may pass if the conditions are favorable. The phenomenon may lead to process failure through overpressure as the paste becomes depleted in liquid via drainage. This process is generally considered undesirable in the extrusion of ceramic pastes (Benbow and Bridgwater, 1993; Blackburn and Wilson, 2008; O'Neill *et al.*, 2016; Bardsley and Bridgwater, 2012; Chen *et al.*, 2000; Chen *et al.*, 1997) and other materials (Bayfield *et al.*, 1998; Wilson and Rough, 2012). On the other hand some liquid flow to the walls can help by providing lubrication. Looking at the literature on filtration, it becomes apparent that phase migration can be minimized by increasing the viscosity of the fluid and/or by reducing the effective porosity. Reducing the porosity increases tortuosity of the channels through which the fluid can flow. By these actions and operating the system close to the minimum fluid volume to avoid bed compaction the liquid tends not to separate from the solid (Benbow and Bridgwater, 1993; Collomb *et al.*, 2004; Draper *et al.*, 1999).

Wall slip

Wall slip is a phenomenon of wall depletion, where due to the higher particle concentration near the flow axis there is a gradient of both solid and liquid contents in the capillary cross-section, particularly as the wall of the extruder is approached. This is caused by different shear stress at the wall and in the center of the capillary, the particles will naturally flow away from a region of high stress at the wall to the region of lower stress in the center. Furthermore as the particles can only approach the wall by point contact there will be a lower volume of solids within half a particle diameter of the wall. Mooney (1931) developed an analysis to quantify the contribution of slip to the overall flow, which is described by Mewis and Wagner (2012a,b). A slip layer therefore exists between the solid boundary and the material inside the die. This layer has a macroscopic non-zero velocity (apparent slip velocity), therefore violating the no-slip condition present in fluid mechanics, for example in Hagen-Poiseuille equation (Fox and McDonald, 1994a,b). There have been attempts at calculating the thickness of the slip layer and its velocity (Khan *et al.*, 2001; Cloitre and Bonnecaze, 2017). Improvements by Jastrzebski (1967), in the form of capillary diameter dependence have been criticized by Martin and Wilson (2005) and Tikhonov regularization has been proposed as a more valid method for wall slip assessment. Even with these refined approaches there are experimental results that show capillary diameter dependence, see Mewis and Wagner (2012b) and citations therein. To eliminate wall slip, roughened surfaces of the die in a capillary rheometer can be utilized. The roughness should be at least equal to the smallest particle size. Where there is a significant difference between the smooth and the rough results, slip can be assumed responsible (Cloitre and Bonnecaze, 2017; Coussot, 2005). Another way of mitigating this effect for ceramic pastes is to impose higher stress upon the paste (higher volumetric flow rate) so that the wall slip is insignificant compared to the bulk flow (Coussot, 2005). Although this phenomenon is detrimental to the quality of measurements it can be exploited to aid the extrusion process by improving sliding of the material on surfaces (a somewhat self-induced lubrication, (Wilson and Rough, 2006)).

Binding liquid and paste characteristics

There is an intimate link between the nature of the liquid and the resulting paste properties and this relationship can be evaluated by capillary rheometry. Calculating the ratio of pressure for the paste to the pressure for the binding liquid and plotting it for different ram speeds can reveal if there is an ongoing interaction between them, Benbow *et al.* (1998).

Air bubble inclusion

This breaks the assumption of paste uniformity and incompressibility. These can be identified on pressure-extension velocity plots when there is a sudden local pressure drop at a constant ram speed, [Amarasinghe and Wilson \(1998\)](#).

Mixedness

Capillary data will be influenced by the mixedness of the paste being analyzed. Not only from the noise within the data, but also it is common to see unexplained non-standard behavior as the paste changes while being extruded.

The calculations and the methodology pertaining to the capillary rheometry is available in several texts: [Benbow and Bridgwater \(1993\)](#), [Cogswell \(1981\)](#), [Draper et al. \(1999\)](#), [Morrison \(2001\)](#), [Williams \(1999\)](#), [Chhabra and Richardson \(1999\)](#), [Gleißle and Graczyk \(2007\)](#), [ASTM International \(2017\)](#) and [Mewis and Wagner \(2012b\)](#). Typical plots for ram extrusion (capillary rheometry) with explanations are presented by [Gleißle and Graczyk \(2007\)](#).

Paste Behavior in Mathematical Expressions

The behavior of paste-like materials can be quantified mathematically using various equations. The first thing to consider is what is going on at the wall of the extruder. If the paste is treated as a uniform continuous fluid then the initial assumption would normally be that there is no flow (no-slip) at the wall as in classical rheological analysis. The favored equation then becomes that of Herschel-Bulkley:

$$\tau = \tau_0 + \kappa_s \dot{\gamma}^n \quad (6)$$

where τ is the shear stress, τ_0 is the yield stress, κ_s is the shear consistency, $\dot{\gamma}$ is the effective shear strain rate, and n is the flow index. If no yield is present [Eq. \(6\)](#) simplifies to the power law relationship. To obtain these parameters as accurately as possible from capillary rheometry, an experiment is run to measure the variance of pressure with extrudate velocity for a number of dies of different length but of the same diameter. The pressure data and shear rate can be calculated readily from that data set but the shear stress must be corrected. Undertaking a Bagley correction accounts for any die entry effects and departures from Newtonian behavior are accounted for through the application of a Weissenberg-Rabinowitsch correction ([Morrison, 2001](#)).

There is however, a body of evidence from flow visualization techniques that suggests that paste-like, particulate materials exhibit plug flow (pure slip at the wall). This assumption leads to a different approach in which the body is treated as a plastic (yield stress approach). Benbow and others ([Benbow et al., 1987](#); [Ovenston and Benbow, 1968](#); [Benbow et al., 1989, 1991](#)) developed an equation for extrusion of paste-like particulate materials. In its early development it contained 4 paste parameters (σ_0 , α , τ_0 and β) taking the form:

$$P = (\sigma_0 + \alpha V) \ln\left(\frac{A_0}{A}\right) + (\tau_0 + \beta V) \frac{ML}{A} \quad (7)$$

where P is pressure, σ_0 is the bulk yield stress, α is the bulk velocity factor, V is the mean extrudate velocity, A_0 is the cross-sectional area of the barrel, A is the cross-sectional area of the die, τ_0 is the die wall shear stress and β is the die wall velocity factor, M is the perimeter length of the die, L is the die land length. Later exponents were added to account for the curvature observed in some pressure velocity data. Giving:

$$P = (\sigma_0 + \alpha_1 V^m) \ln\left(\frac{A_0}{A}\right) + (\tau_0 + \beta_1 V^n) \frac{ML}{A} \quad (8)$$

where m and n are the velocity exponents for the die entry and die land respectively, noting that α_1 and β_1 have different units to α and β . This work was summarized in a book, [Benbow and Bridgwater \(1993\)](#). These equations are fitted to the same data set used in conventional capillary flow analysis. [Eq. \(8\)](#) has been widely applied, examples are: in predicting pressure drop in honeycomb dies ([Blackburn and Böhm, 1997](#)), in forecasting the pressure development in single and twin screw extruders ([Burbidge and Bridgwater, 1995](#); [Botten et al., 2003](#); [McGuire et al., 2006](#)). The parameters were said to be independent of the geometry but there is frequently a significant discrepancy between the prediction and the measured pressure in more complex geometries. [Stitt et al. \(2015\)](#) gives a number of reasons for this, in [Eq. \(8\)](#) the number of input variables are less than the number of fitted parameters and thus the solution is ill-conditioned leading to fitting errors. This is exasperated by using the derived parameters to predict behavior in geometries far removed from those used to derive them. However, the equations developers commented on this issue ([Benbow et al., 1991](#)) and confirmed by [Benbow \(2018\)](#). Thus care must be taken in the use of these equations. With the provisos mentioned the equation remains a useful tool in the evaluation of these complex materials.

There have been attempts to modify the Benbow-Bridgwater model to account for some of these points. [Zheng et al. \(1992\)](#) used computer simulation to develop a modified Benbow-Bridgwater model in which die size is accounted for:

$$P = 2 \ln\left(\frac{D_0}{D}\right) \left(\sigma_0 + a'_b \left(\frac{V}{D}\right)^n \right) + \frac{ML}{A} (\tau_0 + \beta_1 V^m) \quad (9)$$

where D_0 is the barrel diameter, D is the die diameter and a'_b is a modified die entry velocity factor. [Basterfield et al. \(2005\)](#) focus on the die entry term only suggesting Herschel-Bulkley be used for the die land calculation such that the pressure drop for the die entry section becomes:

$$P = 2\sigma_0 \ln \frac{D_0}{D} + A\kappa_u \left(\frac{2V}{D} \right)^n \left(1 - \left(\frac{D}{D_0} \right)^{3n} \right) \quad (10)$$

where

$$A = \frac{2}{3n} (\sin\theta_{\max}(1 + \cos\theta_{\max}))^n \quad (11)$$

and κ_u is flow consistency. This equation requires the selection of the cone angle θ formed by the paste at the entry to the die. The advantage of Eq. (10) is that it has physically meaningful parameters compared to Benbow-Bridgwater.

The assumption of paste uniformity has received significant attention from researchers. The critique of the Benbow-Bridgwater approach extends to the fundamentals from which it was derived, with claims of very poor accuracy even in the field of metal extrusion (Chandler *et al.*, 2002). Others point out the non-uniformity of the paste flow within the barrels/dies. The idealized rheological paste profile, be it more or less shear thinning, may display telescoping segments, i.e., there may be parts of the paste that do not follow the generally described smooth profile from fluid mechanics texts. The liquid between the segments provides lubrication, whereas the segments themselves are in semi-plug flow (Funk and Dinger, 1994b,c). Telescoping layers could be induced by low and high shear rates close to the critical values, i.e., when the paste is sheared slightly above its yield stress or above the dilatant stress (in the shear thickening regime), respectively. Such telescoping segments also contribute to defect formation (see Section “Extrusion Defects”). The authors remark here that this effect may pertain to especially large components like electrical porcelain bodies as observations of smaller extrudates do not present the described features of telescoping.

Of course it must be considered how computer simulations might be used for the analysis of flow during extrusion. The models described so far represent a continuum approach. The Benbow-Bridgwater fits this category but is not represented in most Computational Fluid Dynamics, (CFD) programs. In CFD it is most common to fit a flow model such as Carreau (or derivatives) and adjust the boundary conditions to account for the chosen slip criterion, along with the variation in properties with temperature, noting that not all commercial packages will be able to do this directly. An example of this is given by Cademartori *et al.* (2018) who used the approach to good effect on ceramic injection molding compounds. Of course this is not ideal as the conditions and models do not capture the complexity of the paste system and can lead to some concerns over the results as phase separation and pore pressure are not taken into account. Flow properties are not always captured perfectly when compared to experimental evidence.

The concerns with CFD have led to approaches which consider the behavior by looking at the microscopic structure more closely. This was probably first attempted by Yuan *et al.* (2001). In that work the particles were modeled separately by a Discrete Element Method (DEM) and the fluid then modelled within the pore structure resulting from the DEM step by CFD approaches. This was computationally intensive for the time and not pursued for a number of years after that initial paper. The concept of using DEM has been taken further by Ness *et al.* (2017) who looked at the extrusion of non-Brownian spheres in a Newtonian fluid counteracting the hydrodynamic interactions between the individual particles. They showed good correlation between pressure drop across the extruder and the extrusion flow rate linking the empirical fitting parameters to the practical properties. Surface friction and wall roughness interactions were demonstrated. Dead zones were observed to develop as would be expected from experimental observation and the flow profile appeared well captured. While all looked promising there were variances in behavior on a local scale which were not captured. Some inhomogeneous results for the first normal stress difference calculated inside the die near the entry seemed to indicate a practical way of identifying a possible breakdown of extrudate if the die was to be shortened.

Patel *et al.* (2017, 2018) have taken a different approach to computationally modeling paste flow. Treating pastes as a clay, applying the Cam-Clay model and incorporating a simplified Tresca wall friction condition it was possible to closely monitor the liquid phase behavior in the extruder. It proved useful in seeing how phase migration is controlled by the geometry of the die for example. Other earlier models, such as Khelifi *et al.* (2013) may differ in the predictions of permeability, for the fluid mal-distribution could be calculated with other models than Kozeny-Carman solution (in this case the Taylor model).

As computing power improves, these approaches in combination with method refinement and process understanding point the way to future development. On a practical level the adoption of these more complex computational methods over the continuum approaches looks to be some way off.

Solid Free Form Fabrication

One area of forming that has experienced enormous growth in the last two decades is freeform fabrication. The methods in this category of processing are many and are summarized by Travitzky *et al.* (2014) but almost all take a Computer-Aided Design (CAD) object and section it into layers such that the object can then be built by laying down those layers sequentially in the material of choice. Many of the routes to manufacture do not use extrusion as the method of deposition but there is a small group of techniques that do. Collectively these have been called Extrusion Freeform Fabrication (EFF) but as each variant developed they were given different names to distinguish them. These terms are well reviewed in Travitzky *et al.* (2014) and here their simplified notation will be used. Other reviews on this area include Tay *et al.* (2003) and Yang and Miyanaji (2017). The processes can be more or less subdivided into three approaches which Travitzky *et al.* (2014) name as: Fused Deposition of Ceramics (FDC) in which the feedstock is melted and extruded, these compounds have much in common with injection molding, Robocast (RC) in

Fig. 5 Metering methods for extrusion freeform fabrication, (a) conventional extrusion, (b) needle valve control, (c) auger metering. From Li, W., Ghazanfari, A., Leu, M.C., Landers, R.G., 2017. Extrusion on demand methods for high solids loading ceramic pastes in free form extrusion fabrication. *Virtual and Physical Prototyping* 12 (3), 193–205.

which a suspension or colloidal gel is deposited at ambient temperature and Freeze-Form Extrusion Fabrication (FEF) in which a suspension or colloidal gel is deposited and frozen onto a cooled substrate. It can be said that this technology has its origins in coil pottery making where the object is made by laying down plastic clay strands to build a three dimensional object. Sharma (1967) states that coil building has been practiced since Neolithic times. The innovation in EFF is in carrying out the process in a far more controlled and reproducible way by the use of computing power and carefully controlled formulations.

While shape retention is required in EFF, it is also important that the individual extruding strand adheres to the assembly to bond the filaments together to make the 3D object. The solidification, be that by thermoplastic solidification, drying, gelling or freezing needs to be controlled appropriately for the build process to be successful. By necessity the materials need to have relatively low viscosity at the point of extrusion compared to conventional extrusion, Travitzky *et al.* (2014) states that viscosities should lie between 10 and 100 Pa s but does not give the associated shear rates.

The extrusion process in these systems will start and stop frequently within a layer as the travel path will be designed to develop the fill without overlap thus it is often referred to as extrusion on demand. As such the flow must start and end when required and be of uniform thickness throughout the process. This can be controlled using two approaches. The first is described by Zhao *et al.* (2010) and involves programming the extrusion through adaptive control. The second concerns improved metering. To give greater delivery control, mechanical devices have been introduced between the extruder barrel and the nozzle. Two methods are shown in Fig. 5.

Wang and Shaw (2005) show the importance of colloidal control on the form of the laid down extrudate in extrusion freeform fabrication. The filament morphology is influenced by pH, particle size, extrusion rate and nozzle height and speed. In this area of extrusion there is again a discussion over which is the best flow equation to use. The models that have been applied are largely the same as those discussed in Section “Paste Behavior in Mathematical Expressions”. Wang and Shaw (2005) use for example a power law model and for looking at nozzle geometry Benbow-Bridgwater (in this case for multi-hole geometries). Lui *et al.* (2015) also consider Benbow-Bridgwater and Herschel-Bulkley however, they go on to develop a viscoelastic-plastic model described by a spring and dashpot (Voigt/Kelvin element) in series with a yield-dashpot segment. On the other hand, Li *et al.* (2013a,b) developed a modified Herschel-Bulkley model to help in the aspect of flow and shape retention in the presence of compressibility from air entrapment and compare their findings to experimental data with some success. It would be fair to say that Benbow-Bridgwater in these relatively fluid systems should be used with some caution because of the basic assumption made: to be valid the material needs to be highly plastic and flow as a plug and as Powell *et al.* (2013) have shown this is only truly representative of flow at the highest possible solids loadings before extrusion ceases.

Fig. 6 Alignment of short silicon carbide fibers (30 vol%) in an alumina particulate paste. Left image flow left to right, right image a section perpendicular to flow, fiber diameter approximately 15 μm (adapted from Blackburn, S., Böhm, H., 1995. Silicon carbide fiber-reinforced alumina extrusion. *Journal of Materials Research* 10 (10), 2481–2487).

Extrusion Defects

Ceramics formed by extrusion will be prone to the same defects as those made by any other forming route but of course the process of extrusion can give rise to its own specific defects. These defects arise due to the material flow and include lamination, edge tearing, preferred particle orientation and internal defects (cracking or gas entrapment) (Onoda and Hench, 1978; Händle, 2007).

Particle Re-Orientation

Earlier it was suggested that pastes exhibit plug flow, Section “General Characterization”, but of course where there is a constriction in the flow there will be shear and elongation. Such flows cause non spherical particles in the formulation to rotate and take up a preferred orientation. This orientation leads to differential behaviors in post processing in the axial direction of extrusion compared to the orthogonal directions. Shrinkage and the final properties after firing will be different. This could be advantageous for example in the extrusion of hexaferrites for magnetic property development (Yuan *et al.*, 2002). The image (Fig. 6) shows a short fiber composite extrusion parallel and perpendicular to flow, the alignment of the fibers is clear to see (Blackburn and Böhm, 1995). However, it commonly occurs in clay and alumina bodies because these powders exhibit plate-like form and can lead to other defects such as internal cracking and lamination as a result.

Lamination

Laminar flow is always present in extrusion and this can itself lead to issues where the laminar flow generates a propensity to crack along the flow direction which may result from maldistribution of the phases or flow streams being forced together with little mixing after an obstruction such as a spider arm. In this circumstance the structure may be weakened if the two streams do not knit back together well. Mantle *et al.* (2004) consider the phenomenon with Magnetic Resonance Imaging (MRI) and showed the importance of an extended die land and constriction after the obstruction and that higher extrusion rates could aid in better closure. Blackburn *et al.* (1998) reported a method to evaluate the lamination. Funk and Dinger (1994a) developed a different form of spider legs (Z-shape – corrugated instead of straight) to eliminate the elliptically shaped discontinuities arising from radial body compression. In screw extruders lamination resulting from the paste leaving the end of the screw flight may manifest itself by cracks of a spiral form in the extrudate (Onoda and Hench, 1978).

Edge Tearing

Edge tearing tends to occur more often in dies producing shapes with sharp corners in their cross-section. It is a phenomenon where the material cracks because of internal stress developing through differential flows close to the surface. As a result the surface of the extrudate peels back as flow continues due to the tensile weakness of the paste. The stress is relieved by this process and normal flow resumes for a brief period. This leads to the characteristic repetitive defect form shown in Fig. 7. Domanti and Bridgwater (2000) looked at the origins of this fracture form and showed that it was generally found to initiate at the die exit though occasionally it was seen to propagate back into the die land. They concluded that the defect could not be linked to the rheological properties measured by capillary flow and that tensile strength of the paste is important. In the extrusion of honeycomb monoliths the outer cells may be lost to this type of defect. The onset of this defect type has been detected by pressure signal processing by Russell *et al.* (2003) using fractal analysis to look for patterns in the data. The results from modeling such as those presented by Ness *et al.* (2017) could also be of use when considering the onset of probable material discontinuity due to internal stress differences within the paste in the die land.

Fig. 7 Example of surface tearing in a cylindrical rod nominally 3 mm in diameter, formulated from alumina clay and glycerol for the purpose of illustration by the authors.

Phase Migration

Where phase migration is present but not catastrophic it can lead to defects in the extrudate (see Section “General Characterization” for a discussion of phase migration). Liquid tends to migrate to the die-paste interface and this in combination with a concentration of finer particles close to the wall contributes to defects associated with differential drying and lamination.

Co-Extrusion

Some complex structures have been produced by co-extruding more than one formulation at once. Two methods have been proposed, in the first the pastes are laid up on a larger scale than the final extrudate. The body is then simply extruded and because of the laminar flow the cross-section is reduced while maintaining the cross sectional pattern (Van Hoy *et al.*, 1998). It can be an effective method but because of the time consuming hand preparation it has not been used to any great extent outside Micro-Tubular Fuel Cells (MTFCs). In the second the pastes to be combined are held in different extruders feeding a common complex die through a manifold. Using the methodologies outlined in this review it is possible to generate pastes of different composition with similar rheological behavior which can thus be forced through the multi-channel system in a predictable way. This method has been demonstrated by Powell and Blackburn (2009, 2010) for the extrusion of MTFCs. However, even if the flows are matched defects may form through differential post processing behavior (drying and sintering). Others extend the approach of co-processing for fuel cell systems by using phase inversion technologies, (Droushiotis *et al.*, 2009; Othman *et al.*, 2012).

Concluding Remarks & Other Literature

The reader is referred to other works that summarize well the field of extrusion and highly loaded suspensions, such as Coussot (2005), Wilson and Rough (2006), Blackburn and Wilson (2008), Wilson and Rough (2012) and Kalyon and Aktas (2014).

Acknowledgments

We would like to thank the EPSRC for the studentship and Miss Emma Jones and Mrs Katy Harrison for her help in the development of this work. We would like to thank also all those who have worked with us over the years on the extrusion process.

Ceramic Injection Molding

Moritz v Witzleben, INMATEC Technologies GmbH, Rheinbach, Germany

Tassilo Moritz, Fraunhofer Institute for Ceramic Technologies and Systems, Dresden, Germany

Historical Background

In July 1938, a method for making a refractory body was patented by the US patent office. The inventor was Karl Schwartzwalder (Schwartzwalder, 1938). Independently from this, in November 1940, Klinger *et al.*, 1940, obtained a German patent claiming a method of producing spark plugs by injecting a ceramic compound with the addition of organic binders into a mold by application of pressure. During the first thirty years, however, ceramic injection molding was of minor interest to the wider ceramics industry (Mutsuddy, 1989). The progression into financial viability was based on research and development efforts undertaken during the 1970s and 1980s (German, 2007). Injection molding provided a cost-effective fabrication method suitable for the mass production of the parts of a heat engine whose complex shape caused fabrication problems (Mutsuddy, 1987). For the decade between 2000 and 2009, PIM had generally experienced growth, mostly in the 8%–14% range (German, 2013). Nowadays, CIM is identified as one of the lead technologies in the field of technical ceramics.

CIM Processing Chain

In contrast to the raw materials used for traditional ceramics, which contain clay minerals and therefore showing a pseudoplastic behavior, the powders for advanced ceramic products are synthetic high purity materials with no “plastic shaping” ability. For this reason, the powders must be combined with organic additives to give them the desired plasticity (Moritz *et al.*, 2009). After shaping of components by injection molding into a so-called “green part”, the binder system has to be removed completely for sintering and for attaining the final desired properties of a ceramic component. A schematic processing chain is given in Fig. 1.

The CIM processing chain is explained in more detail below.

Initial Powder

The selection of the ceramic powder is based on the requirements for the material properties of the planned component, its intended use and location and the stresses to which the component may be exposed. There are no limits to the chemical composition of the ceramic powders. These can be, i.e., oxides, non-oxides, silicates, silicides, nitrides and carbides (Witzleben *et al.*, 2008c). Ideally wet milled or chemically precipitated powders with a uniform particle shape are preferred, but for economic reasons cannot always be used due to their high price. As far as possible, raw powders should be free from chemical additives that reduce their surface wetting properties (Schlieper, 2015).

Particle size distribution, specific surface and the chemical composition are the main characteristics of ceramic powders. Powders with a particle size distribution greater than 40 μm are very rarely utilized (Witzleben *et al.*, 2008c). CIM generally uses powders with particle sizes in the range between 200 and 2000 nm and a specific surface between 3 and 20 m^2 per gram. For the control of the shrinkage, however, these characteristics must be specified within much closer limits (Schlieper, 2015).

The main requirements that are placed on powder for ceramic injection molding are:

- Good injection – flow properties without the excessive use of binder
- High sinterability (firing at the lowest possible temperature)
- Constant shrinkage

The proportion of a ceramic powder that can be incorporated into a continuous binder matrix in order to obtain a tight dimensional tolerance after sintering depends on the packaging properties (Witzleben *et al.*, 2002).

Fig. 1 Schematic CIM processing chain.

Necessity of Feedstock and Feedstock Preparation

Key target of feedstock preparation is homogeneity. In this context, it describes two types of homogeneity, related to the composition, i.e., the powder content in the binder and related to the dispersion of powder particles in the binder and the degree of division of agglomerates (Wang *et al.*, 2016). Avoiding the formation of agglomerates is essential for 2 reasons:

- Ceramic agglomerates act as minute porous sponges that trap binder (Trunec *et al.*, 2002) which is then lost for ensuring the rheological properties
- Agglomerates function as defect points in the final sintered components with the result of reduction the ceramic properties of the end part (Hohlbaum, 2019).

The standard of compounding technology involves powder blending and shear roll extrusion (Witzleben *et al.*, 2008a) of the powder-binder mix with subsequent pelletizing (Witzleben *et al.*, 2008b).

Shear roll extrusion is a process that guarantees intimate compounding with a maximum shear rate which is important to avoid agglomerates of the ultrafine ceramic powders, to coat each ceramic particle and obtain a homogeneous product with excellent consistency on a high-quality level. Archiving highest and even green density in the injected part is the precondition for a dense end-contour part finally after debinding and sintering (Hajek, 2015).

Fig. 2 shows the set of two parallel shear rolls. Between the rolls there is a small gap of usually less than 1 mm width. The feedstock, which is fed into the gap at one end of the shear rolls, sticks on one roll and the other roll is clean.

Although the shear roll extruder has a higher energy input in comparison to a twin-screw extruder or a sigma-blade kneader, usually not all agglomerates can be divided (Walcher *et al.*, 1999).

In order to produce high solid loaded submicron and nanoparticle containing feedstocks is suggested to pre-mill, to disperse, and to deagglomerate ceramic powders (Moritz *et al.*, 2010).

Binder Systems and Debinding Concepts

When the powder blend has been determined, the next step is the selection of the most suitable binder for the designated application. The processing of a ceramic feedstock requires polymer components which are able to withstand the severe forces, needed to break up agglomerates. Only a few polymers can be used for this purpose – keeping in mind that they have to have the property of being willingly injection molded with a high load of ceramic powder. The minimal requirements for binder systems include low viscosity to ensure complete filling of mold cavities, relatively high mechanical stability to ensure safe removing from a mold, good shape retention and low shrinkage during debinding and sintering (Hajek, 2015).

Binders are made up of several components (Chartier *et al.*, 2001):

- A basic low molecular polymer for an easier extraction during debinding and as plasticizers (Bleyan *et al.*, 2015) between the long polymer chains of the backbone polymer to lower the feedstocks dynamic viscosity and provide a suitable rheological property to ensure a complete cavity filling during injection of the feedstock into the mold (Moritz *et al.*, 2009),
- A backbone binder for the strength of the component (Hausnerova *et al.*, 2017; Wroblewska, 2001) and
- Often, but not always additives like lubricants or dispersing agents (Chartier *et al.*, 2001).

The aim is to have fewer components than possible in order to reduce the tendency of demixing through the injection molding process due to high injection molding pressures.

Polymers commonly chosen for CIM are polypropylene, low density polyethylene, ethylene vinyl acetate (Edirisingh *et al.*, 1987), polystyrene, polymethyl methacrylate, polyvinyl butyral, polyacetal (Hens *et al.*, 1995) or polyamide (Mannschatz *et al.*, 2014).

Fig. 2 Shear roll used for feedstock homogenization. Courtesy INMATEC Technologies.

Depending on the binder composition different debinding procedures are available. Polyacetal based binders can be debound via a catalytic procedure (in nitric acid containing atmosphere) (Hens *et al.*, 1995) or acetone. In case of the catalytic procedure, an outstanding performance in terms of extremely short debinding times is here to emphasize.

Pure thermal debinding as an alternative is widely used (Burger, 2009; Schlieper, 2016; Trunec *et al.*, 2002). Due to decomposed products need to leave the bulk by diffusion, the heating process has to be carried out very slowly to prevent the creation of internal pressures which cases in cracks and voids in parts (Moritz *et al.*, 2009).

The most common debinding procedure is the combination of a pre-debinding with a solvent (water, acetone, isopropanol, heptane) and a subsequent thermal debinding process (Trunec *et al.*, 2002; Mannschatz *et al.*, 2014). The purpose of solvent debinding is to remove a soluble binder additive to create open porosity. Open porosity allows during the thermal debinding step decomposed organics to diffuse easily to the surface (Hajek, 2015; Schlieper, 2016). By this way, the debinding time and the risk of cracks and voids can be reduced (Mannschatz *et al.*, 2014). Debinding time depends on used solvent, wall thickness and particle size distribution.

The choice of the binder system depends on targeted properties of the part, the amounts to be produced, company and regional regulations and market needs.

Less common feedstock systems are based on carrageenan (Millán *et al.*, 1997), cellulose derivatives (Huzzard *et al.*, 2003) or ceramic precursors including silanes, carbosilanes, siloxanes and silicanes (Wroblewska, 2001).

A further alternative technique for debinding, extraction of organic binders by supercritical fluids has been investigated (Chartier *et al.*, 2001; Chartier *et al.*, 1995).

Injection Molding Process

High pressure CIM is in principle borrowed from the plastic injection molding industry. It can be automated easily and is, unlike other ceramic shaping techniques, suited to high volume production (Moritz *et al.*, 2009). The equipment used for injection molding CIM parts is the same as the equipment that is used in the plastic injection molding industry, with small modifications to reduce wear, like a hardened screw and barrel, and assure homogeneity (modification of screw design and equipment of screw with backflow barrier) during plasticization (Verpoort *et al.*, 1996). For injection the granulated feedstock is fed into the barrel of the machine and heated to produce a semi-fluid mass (see Fig. 3). In a screw machine, a major portion of heat comes from the frictional forces between screw material and cylinder. The semi-fluidized feedstock is then forced into the mold cavity through a gated runner system of the tool. In screw machines the backflow barrier allows the auger to act as a piston, pushing the molding medium into the tool cavity.

At a certain degree of mold filling (approx. 95%–97%), the so-called switching point, the injection pressure switches to hold pressure for avoiding a volume reduction of the injection molded piece due to cooling until the gate of the runner freezes and the part becomes solid. After a specific cooling time (typically 10–300 s) which depends on the volume of the injection molded part and the solidification behavior of the semi-fluid mass the tool opens, and by pushing the ejector system of the machine forward the part is ejected and removed by a handling system in an automated process or simply by hand. The sprue is removed and the CIM part can be put into sintering trays for the subsequent thermal treatment (debinding and sintering). During the cooling step of the part in the closed tool, the screw is pushed back and starts feedstock retraction and metering again for the next shot.

Fig. 3 Schematic view of the injection molding process within the injection molding machine.

For higher productivity in Ceramic Injection Molding increasingly multiple tool cavities are used. When it comes to incorporating multiple cavities in a CIM tool, it is essential that the route of the runner to each cavity is of equal length (Kim *et al.*, 2014). The sprue runner must therefore be branched accordingly. For material saving which would be needed for filling the runner system, hot runner systems can be used. Moreover, hot runners allow to manufacture parts with fewer internal stresses, because green parts that at first appear to be of good quality can possess internal stresses, which may in turn lead to cracks during later processing steps such as debinding (Michaeli *et al.*, 1996).

The temperature control of the injection molding process, especially tool temperature control, plays a dominant role for reliable production and high quality of the injection molded parts. Mainly, CIM processes rely on an isothermal mold temperature to produce parts. Typically, polymer and wax-based molding compounds are heated in the molding machine to temperatures of 130–200°C and are injected using barrel pressures between 50 and 150 MPa. Since the tool temperature is considerably lower than the melting point of the feed material, high injection speeds are required. Without these higher speeds, adequate filling of the cavities cannot be achieved without the premature freezing of the feed material. Accordingly, the mold temperature must be brought to the melting point of a controlled manner during injection. Ultimately, as CIM parts become larger and ever more complex, but also for production of micro parts or thin-walled parts so-called variotherm temperature control guarantees the highest possible part quality of the final product. By switching between defined temperatures, the user can directly influence the surface molding and the solidification behavior of the feedstock (Hohlbaum, 2019).

For tool design, the geometry of a component and the production volume are crucial aspects. They affect the position of the component in the tool and the number of cavities, the design of the runner system, the type and the position of the sprue, the operating mode and the removal of the injection molded parts (manually or automated) such as the ejection system (mold parting surface, core pullers) (Merz *et al.*, 2003). Further, it has to be taken into consideration that ceramic parts typically shrink during sintering by approx. 14%–22% linearly according to the packing density of the green parts. This property is considered as an oversize factor for tool construction.

Defects which result from the injection molding process are irreversible and impair the quality of the finished ceramic components. A comprehensive overview of injection molding errors, their sources and helpful counteractions has been compiled in (Maetzig *et al.*, 2002).

The key value in CIM for component quality and reproducibility is a constant viscosity of the feedstock. The most common way and widely applied in industry to analyze the melt progression in a tool cavity is by producing a short shot study (Karatas *et al.*, 2008; Zhang *et al.*, 1997; Moritz *et al.*, 2010). By interrupting the injection phase at different volumes a sequence of filling stages is created. The obvious advantage is its universal applicability to all tools using normal production conditions. Furthermore, it requires only modest time and cost. However, the produced samples show only the state at one moment and do not reflect the flow pattern in the final part. According to Walcher (2010), an alternative method for feedstock validation on a real injection molding machine by measuring the flow behavior is introduced. In this case the maximum injection pressure at the switching point to the holding pressure in an injection molding machine working under thermal equilibrium conditions is estimated exactly. The used testing tool produces parts while the tool cavity is filled to less than 100% with different injection speeds. The machine control registers the pressure at switch over point. From the pressure values, statements concerning the feedstock quality can be derived which can be applied directly to the machine process parameters (see Fig. 4).

Quality control of ceramic components in the green, debound and sintered state is commonly carried out by weighing and by visual inspection. Combining both simple methods allows for the detection of surface cracks, impurities, pores, voids, distortions, incomplete parts or sink marks. Measuring the density of the ceramic component after sintering is another indispensable method

Fig. 4 Curves which are created with the ARBURG Feedstock test. Source: ARBURG GmbH + Co KG.

Fig. 5 Radiographic image of an injection molded testing part. The flow lines of the feedstock are visualized by means of a so-called tracer feedstock. Reproduced from Moritz, T., 2020. Ceramic injection molding: Developments in production technology, materials and applications. Powder Injection Molding International 14 (4), 3–29.

for characterizing the performance of the injection molded part, because most of the defects introduced in the green body during injection molding either increase or even become obvious after sintering (Moritz *et al.*, 2009).

More precise methods for detecting deviations from the desired geometry or distortion of components are 3D coordinate measuring or 3D scanning. For detecting defects inside components already in the green state computed tomography or simply X-ray radiography are the methods of choice. Entrapped air, voids, cracks, pores, inclusions, impurities, as well as weld lines, powder-binder separations and density inhomogeneities can be detected. A further visualization method uses a tracer material (Mannschatz *et al.*, 2011) which can be detected by X-ray computed tomography. A marker material feedstock that differs in X-ray attenuation but has the same flow behavior is added to the base feedstock during the molding process. Due to inhomogeneous mixing, the flow pattern become visible in CT scans (see Fig. 5).

Process Variants

Low-Pressure Injection Molding (LP-CIM)

According to the type of organic additive and thus the viscosity of the resulting powder-binder-mixtures, the feedstocks are suited to one of two plastic shaping methods. These methods are “low pressure” (LP-CIM) and “high pressure” injection molding. Applied injection pressures between 0.2 and 5 MPa are counted as a low-pressure area of the injection molding process. The advantages of LP-CIM in comparison to high-pressure CIM are:

- Less wear on the machine parts in contact with the powder
- Lower tooling costs
- Easier control of the flow behavior of the batch in LP-CIM

However, several disadvantages limit the use of this processing technology. In particular, defects which may remain in the molded parts after sintering, the difficult debinding step by so-called wicking, i.e., the melting wax component of the binder is soaked by a fine-grained powder bed, and the low degree of automation achievable with this process variant.

Micro Ceramic Injection Molding (MicroCIM)

Besides the distinction between high-pressure and low-pressure ceramic injection molding, a number of variations have been derived from the CIM process. One method – named after the size of the injection molded parts – is Micro Ceramic Injection Molding (MicroCIM) which can produce parts with complex shapes on a large scale and which is particularly used to make ceramic micro-holes. MicroCIM allows the manufacturing of precision products characterized by minimal wall thicknesses of 20 μm , aspect ratios up to 20 or structural details in the range of 50 μm or in certain cases less than 20 μm , with a surface roughness of about $R_z < 0.05 \mu\text{m}$ (Piotter *et al.*, 2001; Sutter, 2009; Petzoldt, 2008). The initial powder requirements for MicroCIM are more stringent than that for conventional CIM. The powder must be homogeneous; and the grain size of the sintered part should be at least about one order of magnitude smaller than the minimum internal dimensions of the micro-component in order to obtain a reasonably isotropic behavior (Bauer *et al.*, 2004). With respect to the surface quality of the replicated structures, the best results have been achieved by using ceramic powders with a mean particle diameter of 0.5 μm or even smaller. To obtain a viscosity of the plastic melt which is low enough to fill even the smallest structural details down to the sub micrometer range, a variotherm temperature conductor is used for

heating the molding tool near the melting point of the feedstock prior to its injection into the tool (Piotter *et al.*, 2009). To improve the precision and the accuracy of surface micro structures such as the homogeneity of injection molded parts, the shaping process can also be carried out as injection compression molding. This means, after injecting the feedstock in the mold cavity, the tool is compressed by a stroke of 0.2–0.3 mm providing an additional embossing step.

As a typical widely used microstructure, micro-holes act as transfer and exchange media in the form of micro-channels or nozzles that can be used as fuel injection nozzles, spinnerets, jet turbine blade cooling holes, printer jets, micro-structures of an array hole in a micro-pump, and micro-hole structures in fiber optic connectors and biomedical filters (Wang *et al.*, 1864; Sen *et al.*, 2005; Hanemann *et al.*, 2009; Su *et al.*, 2014). A further benefit can be obtained when two materials are combined in a micro device and so different functions can be realized. This can be enabled by the so-called two-component micro powder injection molding (2C-MicroPIM) (Islam *et al.*, 2012).

Future Process Variants

With regard to the extension of the potential of CIM, the necessity of new solutions in ceramic due to new component concepts, the pressure of reduction of the development for ceramic components or ceramic systems, a number of variations are in the focus research and development.

Hybridization of Materials

Multi-component Ceramic Injection Molding (multi-C-CIM), In-mold Labeling (IML) and In-mold Embossing (IME).

For more than one decade, material hybrids enveloping two different material classes have increasingly emerged. Combinations of polymers and ceramics are reported by Becker (2010) where the ceramic component has a key position for a certain application, as well as metal-ceramic material combinations (Gal *et al.*, 2019; Yeo *et al.*, 1998a,b). The major advantage of 2C-PIM is the direct combination of two materials with different properties in a single production step, therefore eliminating the need for a subsequent joining process (Petzoldt, 2010). However, combining different materials and processes requires the adjustment of the material properties and a tuning of co-processing and process technology. The co-processing of two materials from the green state to the sintered state involves a number of challenges and demands to be met. Choosing a suitable material couple is one key issue for a successful co-sintering process because chemical and physical properties cannot easily be changed by process adjustments. According to Hohlbaum (2019), the following materials properties need attention:

- Coefficient of thermal expansion (CTE): Differences in CTE lead to stresses in the interfaces during thermal treatment especially during cooling if thermal contraction deviates too much.
- Chemical compatibility: During co-sintering chemical reactions in the interface between the different materials may cause the formation of instable or brittle phases which may limit the long-term stability of the interface.
- Sintering conditions: Both materials should sinter within the same temperature range and atmosphere without melting or decomposition of one partner but still reach desired densities.

In addition, the process technologies each have their individual requirements, which include:

- The properties of slurries, pastes and feedstocks depend on the solid loading, which influences greatly the viscosity. The viscosity in turn effects flow as well as mold filling behavior and therefore defect formation.
- Chemically incompatible binders can lead to delamination between the components. Both involved binder systems have to fit co-debinding conditions.
- When the second component is added, the first component has to withstand mechanical and thermal stresses without deformation or delamination.
- The final shrinkage of the involved materials must be in the same order to keep the stress gradients at a low level. A mismatch of constrained deformation leads to warpage or even defect formation. This can be adjusted by the solid loading which effects the particle packing density in the green body. However, using too high or low solid loadings may cause insufficient flow behavior, warpage during debinding or high residual porosity. Therefore, solid loading has to be treated with care for both partners. It is advantageous to invest high efforts into modifying the raw powders (e.g., by bimodal powder mixtures or alloyed powders) for tailoring the pairing.
- Sintering should start at a similar temperature in order to prevent cracking of the fragile debound body caused by stress gradient.

In two-component powder injection molding (2C-PIM), two feedstocks are used which are adjusted in shrinkage behavior in order to form a two-component part with integrated functions. Several examples of 2C-CIM of different ceramic materials, stainless steel and ceramics, or glasses are shown in Edirisingh *et al.* (1987); Kim *et al.* (2014); Hohlbaum (2019); Karatas *et al.* (2008) and Zhang *et al.* (1997). Up today, up to four different components are combined in this way in the field of powder injection molding.

In-mold Labeling is well-known from plastics industry for instance for the production of yogurt pots with colored labels. As a variant of CIM, a ceramic or metallic green tape made by tape casting or extrusion is inserted into the mold cavity of the injection

molding tool. Afterwards, the CIM feedstock is injected and a material bonding between tape and feedstock is established. Thus, IML allows to integrate a joining step into the shaping process. In the case of use of a micro structured tool insert, the green tape is pushed into these microstructures by the injection pressure of the feedstock. Thus, a micro structured surface of the tape can be attained. This method is called In-mold Embossing. The micro structuring effect can be increased by an additional embossing stroke of 0.2–0.3 mm of the injection molding machine after injection of the feedstock.

After combining tape and feedstock, the completed green part must be co-debindered and co-sintered as known from two-component CIM parts. For that purpose, the binder composition of the tape should be adjusted to the feedstock binder system for a sufficient adhesion between both components and for avoiding detaching of the tape from the injection molded part during co-debinder. Furthermore, the sintering behavior of the tape must be precisely adjusted to those of the feedstock. IML or IME allow for providing injection molded parts with a very thin (approx. 50 μm to 1 mm) layer of a materials with different properties, like different color, electrical or magnetic properties, hardness, or wear resistance. Examples for IML components are described in [Edirisingh et al. \(1987\)](#) and [Moritz et al. \(2017\)](#).

Micro in-mold labeling (MicroIML)

Micro powder in-mold labeling (MicroIML) is a variant of macroscopic in-mold labeling. It is capable of applying a functional material on the surface of a MicroPIM part of complex geometry. For this approach, a thin ceramic or metallic green tape, made by tape casting, is inserted into the cavity of the injection molding tool. Next, the ceramic or metallic feedstock is injected and combined with the green tape by using the applied injection pressure of the feedstock and by a certain inner tool surface microstructure ([Mannschatz et al., 2014](#); [Piotter et al., 2015](#)). After debinding and sintering, the functional material is firmly connected with the substrate material ([Schlieper, 2013](#)).

Hybridization of Forming Processes

It is very difficult to determine the break-even point between CIM and Additive Manufacturing (AM), because there are two main drivers that play a crucial role. For CIM, it is the complexity of the part, which in turn determines the costs of the tool. For AM, it is the size of the part. This determines how many parts can be built in parallel and how long it takes to finish one run. From the viewpoint of the composition of the initial materials, the two feedstock-based AM methods, Fused Filament Fabrication (FFF) and Multi Material Jetting (MMJ), are having much in common with CIM. Both methods can be regarded as close relatives of CIM ([Moritz et al., 2018](#)). Advantageously, both processes can be easily implemented in existing PIM production settings, using the same feedstock preparation machines and expanding the potential range of products through, for example, individualization or personalization. All powders which can be processed by CIM can also be used for FFF or MMJ. Furthermore, the same debinding equipment used in the CIM industry can also be used for the AM components. In the near future, a closer connection between AM and CIM can be expected. For example, parts could be injection molded by CIM, followed by an individualization process by AM. A piece of ceramic jewelry, for example, could be created with unique details. This flexibility could be taken to the point where the end customer chooses or designs individual features which are then applied to a piece of jewelry. This combination of ceramic shaping technologies could also lead to customized medical products covering a very wide range of applications, from dental parts to surgical tools and other medical devices ([Hajek, 2018](#)).

The major advantage of ceramic parts combined by 2 or more materials with different properties is the elimination of a subsequent joining process ([Petzoldt, 2010](#)) and the reduction of the properties of the multifunctional parts by this joining. Property combinations such as conductive/insulating, magnetic/nonmagnetic, thermal conductive/thermal insulating or ductile/hard have been achieved ([Ziesche et al., 2017](#)).

Variothermal Temperature Control

There is a growing interest in the production of larger parts with higher aspect ratios. The main focus of this development is to achieve a faultless surface finish and narrow part tolerances. The key to success in the case of parts with long flow paths and thin wall thickness is to perfectly coordinate the interaction between the mold, the hot runner system and the dynamic mold temperature control system through the use of variothermal temperature control ([Moritz, 2020](#)).

Examples of Materials and Applications

Table 1 shows examples of typical materials and applications made by ceramic injection molding.

Summary

The ceramic shaping process, ceramic injection molding (CIM), is borrowed from the plastics process. The shaping process is particularly suitable for complex, near-net-shape or net-shape components in large numbers. A feedstock, which is processed by means of a shear roll extruder, is used as the basis for the shaping process. The shear roll extruder simultaneously enables the

incorporation of a binder for plasticizing the molding compound and the division of the powder agglomerates. Only in the case of a high degree of dispersion of the agglomerates is it possible to achieve uniform behavior of the feedstock along all value-added steps, injection molding, debinding and sintering. The chapter also shows in which direction the molding process ceramic injection molding is being further developed, in the direction of the hybridization of different materials or the hybridization of different molding processes on the basis of the same feedstock. This means that the process will become more and more widespread in the future.

Tape Casting and Lamination

Tape Casting and Lamination

Tape casting of ceramics was first patented by Howatt in 1952 (Howatt, 1952) for the production of thin capacitor sheets. Tape casting is still one of the primary techniques for ceramic capacitor manufacture today. Tape casting is also known as the “doctor blading” or “knife coating” process since a doctor blade or doctor knife is typically the primary tool involved in the forming process. Other coating techniques such as gravure, micro-gravure, slot die and tension coating are also widely used. The goal of tape casting is the creation of a thin, essentially two-dimensional, sheet from a liquid suspension of particles (ceramic, metal or other). Equipment manufacturers and capacitor manufacturers report tape thicknesses as low as two microns, with fired films as low as one micron. Tapes in excess of three-millimeter thickness can also tape cast, but are generally easier to produce by other methods. The bulk of commercial tape production is between 0.025 mm and 1.27 mm dry thickness with most between 50 and 250 μm .

Single layers of sintered tape, typically 0.1–1.0 mm thick, are used in applications including electronic substrates, porous membranes, monolithic capacitors, wear resistant plates, and electrolyte supported fuel cells. Three dimensional composite products such as multilayer ceramic capacitors (MLCC), packages (MLCP) from both high temperature and low temperature ceramics, ceramic multichip modules, functionally graded materials, and ceramic fuel cells (SOFC and MCFC) are produced by laminating multiple tape layers.

The tape casting process is similar to the slip casting process in that it is a fabrication technique using a fluid suspension of ceramic or metal particles as the forming medium. There are significant differences, however, between the two processes. Modern tape casting often utilizes a high-volatility nonaqueous solvent since the drying process is evaporative rather than absorptive into a plaster mold. There is a balance each manufacturer must consider; the lower cost and environmentally friendly solvent water versus the lower energy needs, increased evaporative speed and increased solubility of other organics offered by nonaqueous organic solvents. Much effort and expense has been undertaken in recent years/decades toward increasing the capability and utility of water-based tape casting. Depending on the unit of measure (tons, companies or acreage) it is arguable whether water based or organic solvent-based tape casting is more prevalent. It is noteworthy that the Howatt patent reported the use of plaster batts as the tape casting surface and that water was the primary liquid vehicle. In the mid-1950s, Park, of the American Lava Corporation, patented the use of a non-absorptive carrier in place of the porous casting surface (Park, 1961). Non-absorptive carriers including polymers, metals and glass are used for the vast majority of modern tape casting, whether aqueous or non-aqueous.

The Doctor Blade Process

The horizontal bed tape casting process, illustrated in Fig. 1, consists of a stationary, adjustable height doctor blade, a moving carrier surface, and a drying chamber. The ‘heart’ of the tape casting process appears to be mechanically simple; however, the design of blades, casting machines, and the slip formulations that make the process work remain subjects of extensive research and development.

Materials Selection

Since the material to be cast is predetermined on the basis of required material properties downstream, organic additives are selected depending upon the powder(s) chosen, often according to the firing atmosphere needed for those powders. The most important selection is that of a binder/plasticizer combination that will yield a strong, flexible tape without damaging final properties after sintering. The binder and plasticizer must facilitate formation of the desired part but burn off cleanly during the pre-sintering operation. Most binder systems chosen are long-chain film forming thermoplastic polymers. Many organic systems meet clean burn-off criteria when the sintering is done in an oxidizing atmosphere at relatively high temperatures, i.e., above 650°C. Many modern ceramic and metallic systems, however, include nitrides, carbides, low melting glasses and reactive braze materials which require the use of organic systems that can be removed in the absence of oxygen and in some cases at temperatures

Fig. 1 Schematic of the doctor blade tape casting process.

Table 1 Selected organic systems for tape casting

<i>Nonaqueous solvent systems</i>			
<i>Solvent(s)</i>	<i>Binder</i>	<i>Plasticizer(s)</i>	<i>Deflocculant</i>
MEK/toluene	Poly(propylene carbonate)	Butyl benzyl phthalate	Z-3 Menhaden fish oil
MEK/ethanol	Poly(vinyl butyral)	Dibutyl phthalate/polyalkylene glycol	Synthetic waxy ester
MEK/ethanol/cyclohexanone	Poly(ethyl methacrylate)	Dibutyl phthalate	Z-3 Menhaden fish oil
<i>Aqueous solvent systems</i>			
<i>Binder</i>	<i>Plasticizer(s)</i>	<i>Cross-linker</i>	<i>Deflocculant</i>
Hydroxypropyl methyl cellulose	Poly(ethylene glycol)/glycerol	–	Ammonium polyacrylate
Acrylic emulsion	–	Poly(oxyalkylene-diamine)	Ammonium polyacrylate

as low as 300°C and in a few seconds rather than in minutes or hours. Acrylic and polycarbonate binders that evaporate or “unzip” upon heating are often used in tape casting systems requiring inert or reducing sintering atmospheres. Commonly used binders for oxidizing firing include poly(vinyl butyral), poly(ethyl methacrylate), poly(methyl methacrylate) and various other acrylic and vinyl copolymers. Other necessary considerations during binder/plasticizer selection include the thickness of the tape to be cast, the surface upon which the cast is to be made, and the solvents desired. Some binders have a greater affinity for and thus adhere more readily to the casting surface chosen. High volatility solvents such as acetone or methyl ethyl ketone (if not water) are often used for casting thin tapes (below 0.25 mm) while less volatile solvents are typically used for thicker tapes to avoid skin formation during drying. The type of solvent(s) used limits the binder/plasticizer systems that can be used (or vice versa) since the binder must fully dissolve in the solvent(s). The ongoing interest in many laboratories and production facilities involves aqueous binder systems to address health and safety concerns. Aqueous tape casting tends to employ non-soluble emulsion binders rather than water-soluble polymers. Extensive lists of solvents and organic additives are available in published literature. [Table 1](#) includes some systems found in literature and industry. As a final consideration in polymer and solvent selection, it has been extensively reported (though published infrequently) that a dissolved polymer in organic solvents tends to retain more tensile drying stress than a water-based emulsion in similar circumstances. This retained stress can have significant impact on downstream processes relying on flatness and positional tolerances.

Tape casting binders typically require plasticizers to improve room temperature flexibility by lowering the T_g of the thermoplastic polymer. It is often beneficial to use dual plasticizers (especially for thicker tapes), one to soften the polymer and a second to lubricate the tape matrix. The primary plasticizer is a low volatility solvent for the binder polymer. The second, non-soluble plasticizer can also act as a carrier release agent. Common plasticizers include various phthalates and glycols. All of the organics should be compatible with each other, if not fully miscible or soluble with the others to prevent segregation during drying.

The selection of a deflocculant/dispersant is also important since the dispersant prevents re-agglomeration of discrete particles after they are broken apart during milling. Proper use of a dispersant/deflocculant permits higher solids in the slurry thus accelerating gel formation and drying in the tape cast product and a more uniform dry tape. A shorter drying time helps to prevent binder segregation and potential density or chemical gradients in the tape as well as lowering manufacturing cost. Organic solvents tend to have low dielectric constants compared with water and thus tend to rely upon the steric hindrance dispersing mechanism to achieve a stable suspension. Aqueous suspensions can make good use of both electrostatic and steric separation forces (see [Lane and Nikles, 2001](#)).

Batching and Slip Preparation

The preparation of slurries for the tape casting process is similar to standard ceramic processing techniques, i.e., ball milling in a dense container with a charge of grinding media. Bead milling, attrition milling, ultrasonic techniques, and basket mills may also be used, among others. A powder dispersion step typically precedes binder and plasticizer addition to optimize both tape density and homogeneity. The purpose of a dispersion-milling step is to break up agglomerates and aggregates and to prevent re-agglomeration prior to binder addition. The solvent(s), dispersant and powder are processed in a jar mill filled approximately to one third with grinding media. The remainder of the charge fills to about one half to three quarters of the mill, which is rotated for 12+ hours. The slurry usually becomes quite fluid during this step due to the activity of the dispersant on particle surfaces.

Binder(s) and plasticizer(s) are dissolved or mixed into the slurry after dispersion milling. The slurry usually becomes more viscous with binder incorporation since relatively high molecular weight binders are used. There are cases, however, where the addition of a binder makes the slip less viscous since the binder can act as a secondary dispersant and replace the dispersant on particle surfaces during mixing. This type of dispersant/binder interaction must be accounted for in the development of a slip formulation and preparation process. Any addition of an aqueous emulsion binder decreases the slurry viscosity due to the water content of the emulsion binder. Non-aqueous dissolution of binder is typically complete within 12–48 h, their aqueous counterparts in less than an hour of low energy mixing. Tape casting slips tend to have a pseudoplastic rheology after all of the components are incorporated.

Slip Conditioning and Characterization

After thorough mixing of all components, the slip is conditioned in preparation for the tape casting process. The first procedure performed after discharging the slip from the ball mill is a de-airing process to remove entrained air introduced during milling, mixing and pouring. Slow rolling without milling media tends to coalesce small bubbles and break large bubbles but is a long procedure that can take up to 150 h to complete at rotational speeds less than 10 rpm. Centrifugation of the slurry concentrates entrained air on one side of the slip body leading to coalescence and rupture, but also tends to concentrate particulates on the opposite side leading to inhomogeneity. The most common technique used for nonaqueous slips is vacuum deairing with continuous agitation or stirring. Vacuum de-airing is done in a vacuum chamber or desiccator under a vacuum of 635–700 torr. The use of higher vacuum pressures can be detrimental to the slip since rapid boiling of the slurry will cause excessive solvent loss and the formation of a solvent depleted layer or skin on the slip surface. Since many water-based emulsion binders are damaged by being under vacuum, this deairing step is done prior to binder mixing if these binders are used. Deairing time is determined by experimentation and depends upon the slip volume and viscosity as well as other factors. Deairing times range from less than eight minutes to a few hours. A good rule of thumb is to use about 4–8 min for a volume of ~ 4 L of 1500cP slurry. A paddle or blade mixer is used to shear the slip during deairing to lower slip viscosity and to help break bubbles on the slip surface.

The deaired slip can be used directly in the tape casting process. Manufacturing processes, however, tend to include a filtration process prior to coating. Filtration is essential when processing tapes below 100 μm . Filtration involves the pumping or pressure feeding of slip through a sieve or series of sieves to remove agglomerates or aggregates not broken down during milling and debris introduced during milling or handling, including pieces of media or mill lining. Filtration also aids removal of air bubbles not removed through deairing. Sieve mesh openings are determined by the critical size of the defect-causing objects being removed, and the final thickness of the tape being cast. The use of submicron filters in 5 μm MLCC tapes is common, while 100 μm filtration is often adequate for thicker tapes or substrates. After filtration, the casting slip is typically pseudoplastic with a viscosity between ~ 500 and 6000 mPa s (cP).

Tape Casting

The heart of the horizontal bed tape casting process is the doctor blade assembly. This assembly consists of an adjustable metering blade with a reservoir to hold the slip. Many variations of doctor blade tape casting exist, all falling into one of two categories, moving blade or stationary blade casting. Most moving blade/stationary carrier machines are used in laboratories or very small-scale production facilities whereas the more prevalent stationary blade/moving carrier systems are used in larger manufacturing processes. The stationary blade configuration permits roll-to-roll continuous production using automated carrier payout and take-up systems. Roll-to-roll processing can then be used in later forming processes if desired. The doctor blade, whether moving or static, is set at a specific height above the casting surface using micrometers or precision shim stock. For casting very thin tapes, or large quantities of a single tape thickness, a precision machined, fixed height doctor blade may be used.

Blade height, or 'blade gap' is one of four primary factors that determine the wet film thickness. The other factors governing this thickness, and thus requiring control, are viscosity, casting speed and reservoir fill depth. The machine operator controls as many of these parameters as possible and then adjusts the blade gap as the last measure of thickness control. The viscosity, being temperature dependent, can be controlled by controlling slip temperature during casting, though it is more common not to do so and to adjust blade gap to account for lot to lot changes in viscosity. Control of reservoir height behind the doctor blade is often automated using a sensor to detect slip level in concert with a feed valve to modulate replenishment slip flow into the reservoir. Since the ratio of doctor blade height to dry tape thickness can vary from unity to 2.5, trial and error is often the only means to achieve the final desired thickness. The wet thickness of a tape can be monitored using laser or optical reflection, gamma backscatter equipment or other non-contact methods. If thickness monitoring is done just downstream from the doctor blade, a feedback loop to the slip level sensor can adjust reservoir depth and thus control wet film thickness very accurately. The expense of doing this, however, makes it a rare feature in industrial tape casting.

Typical doctor blade assemblies consist of one or more rigid blades mounted on a (typically aluminum or plastic) frame. The frame assembly also defines the reservoir that holds the slip. Many different shapes of reservoir and the metering edge of the blade have been reported ranging from a standard box shape with flat bottom blade to a rounded bar to a 'comma' shape with fitted reservoir walls. Angular and parabolic blade bottoms find use mainly in laboratory operations. From a practical standpoint, the use of a flat-bottomed blade has been preferred since it maintains dimensional integrity for a longer time compared to other blade shapes. The thickness of the blade along the casting direction at the casting interface (blade bottom) has also been varied from a knife edge to over three inches depending, apparently, on individual preferences. Some major considerations influencing blade design include: weight, lifetime, ability to mediate reservoir height fluctuations and cost of refinishing. Some tape casters use a double doctor blade – two metering blades in series – in applications where very close tolerances must be maintained. In theory, the first metering blade defines a very precise, if very low, reservoir that aids in the uniformity achievable by the second blade. The net gain achieved by using a double blade versus a thicker single blade remains in debate.

As mentioned earlier, coating or 'slip laydown' techniques other than doctor blading include gravure, micro or reverse gravure, slot die coating as well as "waterfall" coating. While doctor blade and waterfall coating are nearly always performed on horizontally or near-horizontally oriented machines, gravure or slot die coating can be done on a significant incline, vertically or even upside down, depositing the slip on the underside of the carrier film.

Regardless of design or orientation, the coating mechanism meters the slip onto a moving carrier film that transports the deposited slip into a controlled atmosphere drying chamber. The carrier film itself is chosen based on several factors including non-reactivity with the slurry, surface quality, surface finish, cost, stiffness, tensile properties under drying conditions, and ease of dry tape release. Common carrier materials include plain, corona treated, fluorinated or silicone coated Mylar®, plain or silicone coated polypropylene, Teflon®, carbon steel, stainless or valve steel, or polymer- or wax-coated paper. The carrier film is required to withstand downstream drying conditions such as elevated temperatures without degrading the desired properties or characteristics of the cast tape. Very thin thermoplastic carriers, for example, can exhibit excessive tensile yield under elevated drying temperatures and thus degrade tape quality. Products such as thin-film electronic substrates that have specific surface finish requirements may be cast on very smooth carriers since the tape surface dried against the carrier film then displays a lower as-fired surface roughness than the air-dried surface.

Casting speed is typically determined by the length of the drying chamber (or vice versa), the thickness of the tape being cast, and the volatility of the solvent system used. Typical speeds for casting can range from 15 cm min^{-1} to over 5 m min^{-1} . Extremely thin tapes dry more rapidly and thus can be cast at speeds in excess of 10 m min^{-1} , or even upwards of a meter per second.

After a thin, uniform slurry layer is deposited onto the carrier film, the tape is dried to remove the solvent(s). Since the slip is supported on an impermeable carrier, evaporation occurs from only one side of the tape, potentially leading to gradients in solids loading, porosity, and organic constituents. These gradients can significantly affect densification later in the process. Various heating profiles, slurry solids loading and/or organic compositions, air flow rates, location of heating sources (above vs. underneath), and the use of azeotropic solvent mixtures have been explored to avoid compositional gradients during drying of tapes. While gradients can be minimized by combinations of the above approaches, the one-side-drying inherent in the tape casting process makes the formation of gradients through the tape thickness inherent as well.

The use of flowing air speeds the drying process by maintaining low solvent vapor concentrations in the local atmosphere. Local safety regulations may also mandate a maximum vapor concentration allowed. Air used for drying is often filtered to remove dust particles and may be preheated to maximize tape drying rate. Airflow is typically directed countercurrent to the casting direction to form both a solvent vapor gradient and a temperature gradient within the drying chamber. If heated air is used, a hot air inlet at the end of the drying chamber results in a maximum temperature at the end of the drying process to remove remnant solvents while allowing a lower temperature at the beginning of the drying process to minimize skinning or 'case hardening'. Drying can also be accelerated by the use of underbed heating and/or overhead radiant heating to heat the wet cast. Underbed heating is very common, while air heating and overhead heating are rarer.

Shaping

The green tape, after drying, is a strong, flexible sheet of thermoplastic polymer filled with ceramic, metallic or other powder. Due to the evaporative drying process, green tapes also typically include 5%–25% porosity or more. Green densities of 50%–65% of theoretical are routinely achieved for both ceramic and metal powders. This green density can be further increased by reducing the porosity of the green tape through pressing or calendaring. Calendaring, though uncommon, reduces the tape porosity by compaction between two counter-rotating rollers. It can also be used as a partial solution to the compositional gradients mentioned earlier, though the perceived benefit seldom outweighs the cost. Pressing, similar to lamination described below, also reduces porosity and corresponding density gradients.

Long lengths of cast tape are typically cut or 'blanked' into manageable sizes by either cutting the tape, or stamping with a tool and die. The resulting 'blanks', 'sheets', or 'cards' may be sized to include alignment or registration holes around the perimeter and are often sized to manufacture multiple small parts from a single sheet. The blanking process also avoids use of the cast tape edges which are tapered in thickness and thus unusable. Single layer substrate applications blank desired green substrate sizes and sinter at this point.

Tapes used in three-dimensional interconnected circuitry, such as MLCP's, are punched with through-holes at this stage. These holes, or vias, are typically made using punch and die but can also be made with water-jet, laser or microdrill. The vias are then filled with conductive ink. Circuit patterns are also added to each tape layer by screen printing conductive ink(s) onto the unfired blanks. Alignment through each of these stages is paramount and is accomplished by either mechanical (registration holes) or optical (registration marks) means. Some high-performance applications require positioning with better than $5 \mu\text{m}$ accuracy. Stacking and alignment of the metallized layers forms the three-dimensional structure (Fig. 2). Tape layers are often tacked together at this point to preserve alignment through further processing.

Lamination

A low temperature lamination process fuses multiple tape layers into a single, composite structure. This structure typically either includes multiple material types, or includes internal screen-printed conductive features. Laminates containing over 200 individual layers are not uncommon for MLCCs. Lamination methods vary depending on both the tape properties and final part requirements. The four most common approaches are uniaxial, isostatic single plate (wet bag), Isostatic double plate (wet bag) and tape

Fig. 2 After via punching and metallization, tape layers are stacked to form a three-dimensional, interconnected circuit within the ceramic material.

Fig. 3 Individual tape layers are formed into a single part by: (a) uniaxial lamination, (b) double plate isostatic lamination, (c) single plate isostatic lamination, and may be pre-laminated by (d) a tape transfer process.

transfer (**Fig. 3**). Lamination pressures range from 3 MPa to over 50 MPa while temperatures are generally kept below 100°C, often between 60°C and 90°C. In an ideal case, individual tape layers are no longer discernable in the laminate.

Uniaxial lamination, the simplest lamination method, fuses single tape layers together by the application of pressure and heat through two opposing heated platens. The edges of a tape stack can be constrained by die walls or left unconstrained during lamination. Isostatic lamination applies uniform temperature and pressure to all surfaces of the tape stack by means of a wet bag isostatic press with a heated fluid bath. Isostatic lamination is more widely used than uniaxial lamination in manufacturing environments due to uniform application of pressure and the resulting increase in laminate uniformity. Tape layers are protected from the fluid bath within a protective, vacuum sealed envelope or 'vacuum bag'. Vacuum sealing of the bags also avoids air pockets between tape layers and ensures full contact of one layer to the next. The use of a fluid bath in isostatic lamination also allows the lamination of multiple, separately sealed stacks in a single pressing. It is typical in isostatic lamination to use a rigid backing plate (often anodized aluminum) to maintain flatness of the stack after being laminated in the fluid bath. While the face against the backing plate is flat and smooth, the pressed face of the stack typically shows topography in accordance with any internal features in the stack such as screen-printed circuitry. Using two rigid plates, top and bottom of the stack, in the isostatic lamination process is often known as "double plate lamination" and is a hybrid of uniaxial and isostatic lamination. This method still uses the vacuum bag, avoiding trapped air bubbles between layers, but trades the uniformity of pressure offered in order to achieve a laminated stack having flat top and bottom faces with minimal topography. The tape transfer process, sometimes used as a pre-lamination 'stack and tack' process, applies layers to the stack one by one, typically pressing at a lower temperature and pressure than final lamination. This stack and tack process facilitates automation of the stacking process while maintaining alignment of the layers and internal features.

Laminates are considerably more rigid than individual tape layers due to the increased thickness and reduction of internal porosity. This increased stiffness allows for a multitude of possible cutting operations to separate an array of smaller parts. Dicing of multicomponent laminates, or simply edge trimming of single component laminates, is accomplished by gang saw, laser cutting, or hot knife cutting. Hot knife cutting, guillotine separation using a heated bed and heated knife, is far and away the most

common method for singulation of green multicomponent arrays due to the desirable balance of speed, cleanliness, and cost. Gang saw is rarely used due to speed, cost, and potential contamination considerations. Laser cutting is most often used for shapes with non-straight edges. Green laminates can also be scored or perforated with rows of vias to create weakened areas between components. The creation of these weakened areas in a multicomponent array allow the array to be sintered as a single part and snapped apart easily after the sintering process.

Freeze Casting

Dominique Hautcoeur, Belgian Ceramic Research Centre, Mons, Belgium

Introduction

Porous ceramics are widely used for SOFC (Chen *et al.*, 2012), thermal barrier (Scheffler and Colombo, 2005), filtration (Gauckler *et al.*, 1985), ceramic metal composites (Hautcoeur *et al.*, 2016), and so on applications. They are usually fabricated through foaming techniques (direct or indirect) and replica from natural as wood or organic as PMMA beads or sponge matters (Studart *et al.*, 2006). A thermal treatment is done for removing the template which leads to the formation of the porosity inside the material.

Freeze casting is a more recent technique which has been developed for a couple of decades, even if its first utilization is older (Smith-Johannsen, 1994). Freeze casting is a technic to process porous material, but also used to obtain dense specimen (Araki and Halloran, 2004). Freeze casting consists of freezing a suspension of particles down to the solvent solidification and removing it by solid solvent sublimation. The green part so obtained is sintered, without debinding owing to the small quantities of organic additives.

Depending on the device, isotropic or anisotropic porous specimen can be processed. The control of this porous structure is a difficult challenge. Indeed, a series of parameters, such as powder content, freezing rate and so on, have a direct impact on the structure characteristics (pore size, porosity, ...). Most of the studies carried out on freeze casting are concerned by the processing of anisotropic porous ceramics. This chapter will also be focused on this aspect.

How Does it Work?

During solidification of a liquid, the creation of a stable crystal starts with the formation of a nucleus from which the crystal can grow. Nuclei are stable germs (clusters of molecules) that act as interfaces for the condensation of additional molecules. If the nuclei are formed by an accumulation of molecules of the cooled liquid, the nucleation is named homogeneous or spontaneous. In all other cases (nuclei formed by particles, onto surfaces, ...), nucleation is called heterogeneous. Homogeneous nucleation of ice occurs at temperatures of about -40°C (Tremeac, 2005).

For freeze casting process, nucleation is mainly heterogeneous (Deville *et al.*, 2010), indeed the size of ice crystals depends on the ceramic particle size, as it has been observed for a constant particle number. The smaller the particles are, the greater the number of nucleation sites, which promote nucleation over growth. Nevertheless, the roughness and nature of the cooling medium do not influence nucleation (Donchev, 2005). However, it has been observed that the macroscopic organization of the pores can be modified by the texturing the cooling support surface or by the presence of a preformed layer of ice (Munch *et al.*, 2009).

During solidification, limit between solvent crystals created and the remaining liquid forms a solidification front. As described by Mullins and Sekerka's theory (Mullins, 1964), in the early state this front is flat and then could be destabilized. During the freezing of a ceramic suspension, two cases occur, depending on the stability of the solidification front. In the absence of destabilization (flat solidification front), the ceramic particles are pushed forward of the front, as illustrated at Fig. 1. This leads to the separation between the solvent and the particles and the formation of a powder compact. This phenomenon can be used to obtain, after freeze drying and sintering, dense part.

If destabilization of the front occurs, the particles can, under given conditions, be ejected laterally which leads to the creation of a lamellar structure, which after freeze drying and sintering, makes it possible to obtain anisotropic porous materials. In this particular case, the phenomenon of interaction between the solidification front and one or more particles have been widely studied for the past 30 years (Korber *et al.*, 1985; Shanti *et al.*, 2006; Deville *et al.*, 2009a). In the case of a particle close to the solidification front, three interactions are possible, as shown Fig. 2:

- Capture of the particle by the front of solidification: called " engulfment", which can occur even if the solidification front is stable (Fig. 2 particle 1).
- Ejection of the particle between the crystals of the solidification front (Fig. 2 particle 2).
- Ejection followed by a capture of the particle by secondary dendrites (Fig. 2 particle 3).

Only the ejection of the particle is wanted to produce anisotropic porous part, the engulfment of the particle is to be avoided. Indeed, this phenomenon causes an accumulation of particles in the solid solvent which could obstruct the porosity after lyophilization and sintering of the porous material. If we consider the interaction between a particle and the solidification front, its engulfment or ejection depends on the couple of forces involved during the freezing: the attraction (F_a) and repulsion (F_r) forces, define by Eqs. (1) and (2) (Korber *et al.*, 1985), respectively.

Fig. 1 Diagram of oriented freezing: obtaining the lamellar structure.

Fig. 2 Diagram of Interaction between particles/solidification front.

$$F_a = \frac{6\pi\eta vr^2}{d} \quad (1)$$

$$F_r = 2\pi r \Delta\sigma_0 \left(\frac{a_0}{d}\right)^n \quad (2)$$

with η the slurry viscosity, n an exponent value between 1 and 5, a_0 the average intermolecular distance and $\Delta\sigma_0$ interfacial free energy.

If the liquid film becomes too thin, there is contact between the particle and the solidification front, which will lead to the engulfment of the particle. This occurs when the attractive force becomes larger than the repulsion force or when the velocity of the solidification front exceeds a critical velocity V_c defined by Eq. (3):

$$v_c = \frac{\Delta\sigma_0 d}{3\eta A} \left(\frac{a_0}{d}\right)^n \quad (3)$$

with A , a characteristic quantity depending on the shape and size of the particle. Even if the front is stable, a velocity of the freezing front higher than the critical velocity will lead in the same way to an engulfment of the particle.

Considering the importance of the freezing front velocity, the temperatures involved during the process need to be well controlled. For that reason, several types of equipment have been developed.

How is it Possible to Process Porous Ceramic by Freeze Casting?

Isotropic porous materials are obtained by putting the slurry within a mold in a freezing device without any control of the solidification. For example, the freezing step can be performed directly inside a freezer. Moreover, if the slurry is put on a one side metallic plate (thermal conductor part) and polymeric mold (thermal insulator part) is used and placed in a freezer anisotropic structure could be obtained.

Fig. 3 Diagram of the classic freeze casting device.

Fig. 4 Diagram of one side freeze casting device.

Several devices have been developed for controlling the solidification, or not, in order to obtain the porous anisotropic ceramic, all of them coming from the same original device. Indeed, devices are always divided in 3 parts: a mold for casting the slurry, a metallic plate where is settled the mold, the frozen media which might control the freezing step. In this way, basic device is simply a polymer mold place onto a metal plate which is frozen by liquid nitrogen (Fukasawa *et al.*, 2001), as described by Fig. 3.

In order to have a better control of the solidification of the slurry, a one side cooling device is used. The only modified part, in comparison with the basic device, is the freezing media system. Indeed, instead of using liquid nitrogen which leads to a fast and uncontrolled freezing, a cryostat, or heating element can be placed on the metallic plate. The first one can be employed for reaching a cooling freezing rate between 0.5° and $10^{\circ}\text{C min}^{-1}$. The second one, heating systems, can be used to reach faster freezing rate as $20^{\circ}\text{C min}^{-1}$ (Zhao *et al.*, 2011) as illustrated by Fig. 4.

Another way to ensure a good control both of the temperature and the structure is to regulate not only one side but two sides. A two-side cooling device leads to obtaining a control of the thermal gradient (Deville *et al.*, 2007) which is kept constant during all the freezing step. The device is composed of two metal fingers which are immersed in alcohol frozen by liquid nitrogen. The thermal regulation is ensuring by two heating elements for each metal finger. This system has been used to determine the effect of the freezing parameters on the pore size evolution.

An alternative two-side cooling device has been developed (Waschkies *et al.*, 2009). Instead of controlling the thermal gradient during the freezing step, the temperatures are regulated at both side in order to control the freezing front velocity. Several thermal sensors are placed in the mold to follow temperature along the specimen. By this way, it is possible to regulate not only the temperature but also the freezing front displacement. The interest of this technology is the ability to change the freezing speed or keep it constant in order to control the structure. Indeed, it has been shown that the structure is dependent of the freezing front velocity and by controlling it, you control the pore size evolution.

“Hybrid” technologies or special device have been setup for special applications. Basically, those techniques were set up for obtaining special shape of the sample or of the macroporosity. The simple way to control the macrostructure orientation is to swap the material for the freezing and isolated parts. Indeed, using metallic mold can induce a freezing of the slurry by the side instead of by the bottom (Moon *et al.*, 2002).

Further research has been conducted on the use of the dipole moment of the water molecule or the magnetic properties of the powder used to carry out the freezing step under electric (Tang *et al.*, 2010; Zhang *et al.*, 2009) or magnetic field (Porter *et al.*, 2012).

In the case of aqueous suspensions, imposing an electric field in the freezing direction makes it possible to control the thickness of the walls (Tang *et al.*, 2010). In addition, a radial field (perpendicular to the freezing direction) causes a change in the direction of ice crystals growth. The same type of effect is observed during the freezing of the suspension containing iron oxide particles under a magnetic field (Porter *et al.*, 2012). Another example of hybrid technology is the processing of porous film for membrane applications made by a freeze tape casting technology. This consists of freezing a tape after its processing by tape casting (Rachadel *et al.*, 2017).

How to Control the Porous Structure?

In addition to the freezing rate, which is controlled by the device, other parameters influence the structure of the final material. The structure is divided into 4 main characteristics: the porosity level, the pore size, the wall thickness and the structure morphology. In order to control these characteristics, the researcher has several strings to its bow: the amount of dry matter, the solvent, additive, freezing parameters and so on.

Freeze casting can be achieved by employing many solvents which have the particularity to solidify at different temperatures and specific porous structures are obtained. The three main solvents used are: tert-butyl alcohol (Sofie, 2007) with a melting temperature (T_m) of 25°C; camphene ($T_m = 51^\circ\text{C}$) (Lee *et al.*, 2008), or water ($T_m = 0^\circ\text{C}$) (Lasalle, 2011).

In the case of tert-butyl alcohol, the microstructure will be of centro-symmetric with prismatic pore (Sofie, 2007; Choi *et al.*, 2012). Freezing a suspension of a powder content of 10% in volume lead to obtaining a pore size around 140 μm (Choi *et al.*, 2012). It has been shown that in the case of tert-butyl alcohol, there is a pore size gradient along the freezing axis (Hu *et al.*, 2010) (freezing direction imposed by the thermal gradient).

The second solvent, camphene, is used for its high melting temperature (Araki and Halloran, 2004) which allows to sublime it at room temperature. As for the previous solvent, the pore size is high and varies from 140 to 280 μm as a function of the freezing time, from 1 to 7 days (Yook *et al.*, 2009). The porous structure is cellular because of the dendritic solidification of the solvent.

Water is still the most used solvent (Deville, 2007). As described in the literature (Ananth and Gill, 1989), ice crystals grow in the shape of an ellipse, which explains the morphology of the pores. However, the use of additives (Sofie and Dogan, 2001) may result in a change in morphology. These additives, commonly used as binder (Deville, 2007) or cryoprotectant (Zhang *et al.*, 2010), change the lamellar morphology previously described into more cellular morphology, similar to that obtained for camphene suspensions. For example, it has been shown that the addition of 10% of glycerol strongly modifies the morphology of the structure without variation of the porosity level (Zhang *et al.*, 2010).

Since water is the most used solvent, the following paragraphs will detail the studies with water carried out on the parameters influencing the main characteristics of the porous structure.

The stability of the solidification front is at the origin of the defect presence in the structure. After sintering and cutting a sample, heterogeneity of the morphology of the structure can be observed as shown by Fig. 5. Close to the freezing source, a dense area is observed. Beyond this zone, a cellular type transition zone is observed before obtaining the conventional lamellar morphology when using water as solvent. The formation of this dense zone was initially explained by the formation of a stable solidification front that push particles, as Mullins' theory (Mullins, 1964) predicts. However, in-situ observations of the structure formation were performed to determine the real cause for the formation of the dense zone.

The solidification front rate was measured during the first freezing moments of an alumina suspension by tomography (Deville *et al.*, 2009b). The ratio between the freezing time and the size of the frozen zone was used to estimate that the initial speed of the front is about of 750 $\mu\text{m s}^{-1}$. At this velocity, even if the front is stable, it will engulf all particles, which will lead after sintering to the dense zone, which is in fact porous with isotropic morphology. As the solidified layer grows, the velocity of the solidification front decreases very rapidly. This leads to the formation of a transition zone between the dense and lamellar zones, characterized by a porous structure with isotropic cellular morphology, which corresponds to the second zone.

The formation of the zone with cellular morphology was also observed by X-ray tomography (Deville *et al.*, 2009a,b; Lasalle *et al.*, 2012a,b). The authors explain that, during the first moments of freezing, not all ice crystals are oriented in the same direction. They identify two types of crystals: the first ones that will favor the lamellar morphology because their growth is oriented in the same direction as the thermal gradient (Type Z). The second type of crystals is oriented according to the other directions (Type R). The transition from cell morphology to lamellar can be described in several stages:

- Formation of both types of ice crystals in the same proportion.
- Decrease in the number of R-type crystals (growth stopped) at the expense of Z types, which leads to the start of lamellar morphology.
- Suppression of second type crystals.
- The structure remains lamellar until the end of freezing, beginning of steady state.

Another type of defects was observed by X-ray tomography during freezing. This is the formation of ice crystals perpendicular to the thermal gradient (Deville *et al.*, 2009a) during the stationary regime (lamellar growth). After lyophilization, these crystals generate cracks in the walls that would lead to a decrease in mechanical strength (Lasalle *et al.*, 2012a,b). The presence of excess

Table 2 Impact of processing condition on the wall thickness

Parameter	Variation of the parameter	Impact on the wall thickness
Freezing rate	1–10K min ⁻¹ Hunger et al. (2013)	5.8–2.8 μm at 1K min ⁻¹ and 0.55–0.32 μm at 10K min ⁻¹
Powder content	5% to 20% vol Fu et al. (2008)	8–25 μm at 253K
	20% to 40% vol Pekor et al. (2008)	31–28 μm at 233 K and 6–9 at 77K
	11% to 30% vol Liu et al. (2010)	4–17 μm at 77K
Particle size	0.4–10 μm Hunger et al. (2013)	5.8–0.55 μm at 1K min ⁻¹
Binder	PEG Pekor et al. (2008) de 0%–6%	25–30 μm at 233K and 8–10 at 77K

**Fig. 7** Relation between porosity level and powder content.

dispersant or binder seems necessary to avoid this problem. They propose that under, given conditions, the solidification is metastable which lead to the porous lamellar structure. If the conditions switch into the unstable zone, then cracks are formed perpendicular to the solidification front direction. Moreover, during freezing, the ice crystals preferentially grow in the direction of the thermal gradient. At low speed of movement of the solidification front, a supercooling zone is present in front of the latter. In this zone, it is possible to observe a nucleation of ice crystals. The growth orientation of these crystals can then be in other directions than that imposed by the thermal gradient (because of the supercooling zone). Ice bridges are thus formed between the main crystals which will become, after freeze drying, cracks in the ceramic wall as shown at [Fig. 6](#).

Many parameters can influence the pore size ([Pekor et al., 2008](#)): the freezing rate ([Munch et al., 2009](#)), the dry matter content ([Farhangdoust et al., 2013](#)), the particle size ([Waschkies et al., 2011](#)), the sample size ([Pekor et al., 2008](#)), the amount of additive and its nature ([Lasalle et al., 2012a,b](#)).

Table 1 summarizes the impact of these parameters on the pore size. The value of the pore size corresponds to the small diameter of the ellipsoidal pore as schematized by [Fig. 5\(b\)](#). Note that for the data presented in this table, the other parameters than the one studied can be very different, which explain the differences between the obtained values.

In addition to the pore size, one of the important features is the thickness of the walls (Deville, 2007). Factors modifying wall thickness (Hunger *et al.*, 2013) are freezing rate, particle size, dry matter content and binder content (Pekor *et al.*, 2008). Table 2 summarizes the impact of these parameters on the wall thickness.

The porosity level of an anisotropic porous specimen is mainly dependent on the powder content as shown in Fig. 7. Indeed, the porosity is generated by ice removing during the freeze drying. It explains why the freezing parameters (freezing temperature and rate) have very few impact, on the porosity level.

What About the Mechanical Properties?

Considering the anisotropic macrostructure, freeze casted specimens present a great interest for mechanical applications. A significant effect of the orientation of the structure on the compressive or flexural strength was observed (Munch *et al.*, 2009). A compressive strength parallelly to the freezing direction 15 times higher than in the perpendicular direction was obtained. Analytical models were often used for predicting the relation between the structure and the mechanical properties. Exponential model adapted from isotropic porous models (Gibson and Ashby, 1999) have been used in compression (Zhao *et al.*, 2011) and in flexion (Xia *et al.*, 2012). However, these analytical models were developed only as a function of the porosity level, without any adjustment for the pore size, shape and orientation.

In the literature, the characterization of the compressive strength is the most measured mechanical property. Biomaterials such as hydroxyapatite are often used as study materials. Thus, a comparison between isotropic and anisotropic porous hydroxyapatite has been performed (Deville *et al.*, 2006). This study shows that isotropic materials have a compressive strength of less than 40 MPa for porosity levels between 40% and 80%. In comparison, porous specimens prepared by freeze casting tested in compression along freezing direction have compressive strengths of between 60 and 120 MPa, with a porosity level higher than 50%. However, for this study, only the porosity level is considered. Indeed, the pore size, the porosity of the ceramic walls, the morphology of the structure should also be taken into account. In this case, it is found that the reduction in pore size (Farhangdoust *et al.*, 2013) or porosity level (Liu *et al.*, 2010; Farhangdoust *et al.*, 2013) seems to favor a better compressive strength.

Other materials have been studied (Yoon *et al.*, 2008; Zhang *et al.*, 2013) such as alumina or zirconia. A complete study on zirconium boride (ZrB_2) has also been achieved (Landi *et al.*, 2013) for which the compressive strength was deep impacted by the modification of pore size, porosity level and wall thickness. The conclusions are generally the same whatever the powder nature.

A last parameter was studied, the amount of binder introduced into the suspension. Thus, in the case of zirconia, it has been shown that without a binder, the samples have a low compressive strength of the order of 20 MPa for a porosity of 35% (Zuo *et al.*, 2008). The addition of a binder (PVA) leads to a compressive strength of 60 MPa, despite an increase in the porosity level (50%). This result is attributed to a decrease in pore size from 100 μm to 2 μm due to the binder content increase from 0% to 6%.

Introduction

Solid freeform fabrication (SFF), Rapid Prototyping or 3D printing, describe a class of technologies, i.e., additive manufacturing technologies, in which a part is directly generated from a virtual model by adding material to form the part. Additive manufacturing is defined by [ISO/ASTM 52900 \(2015\)](#) (Additive manufacturing – General principles – Terminology) as the “process of joining materials to make parts from 3D model data, usually layer upon layer, as opposed to subtractive manufacturing and formative manufacturing methodologies” ([ISO/ASTM 52900, 2015](#)). According to the philosophy of AM, the choice of a 3D computer graphic, 3D model, and material system is sufficient to build a part. Consequently, it is possible to generate parts with arbitrary geometries without the need of adapting the typical manufacturing process itself. AM of ceramics has the potential to open new markets for ceramic products, as it is not strictly bound by the paradigms of ceramic processing, such as high processing cost for small lot productions, low flexibility, complex machining and limited molding shaping technologies.

Preferably, parts ready to use, i.e., possessing the final physical properties of the desired object, are generated using AM technologies, but also the manufacture of semi-finished parts, requiring additional processing, has turned out to be technically and economically feasible. The material (feedstock) is typically fed into the process as a powder/granulate, filament, paste or suspension, that is, the material is in a state optimized for the layer deposition process. In the manufacturing process itself, the material is used to build up the desired object and it is simultaneously transferred into a state possessing its final physical properties, or at least a mechanical strength sufficient to transfer the built object to further processing steps. According to the needs of the particular material used, the desired geometry or the purpose of the object being built, an entire set of AM technologies has been developed. Polymeric, metallic, ceramic materials and composites can be all processed by these technologies. The initial motivation for the development of rapid prototyping technologies, that is, technologies for the manufacturing of individual products without any requirement for dedicated tooling, was to reduce the time to market of new products by shortening the time span between design, testing and implementation. While in the 80s and 90s the basic technologies for AM were envisioned and flexibility in design was first priority for their development, nowadays the physical properties of the parts generated are a major concern. Accordingly, the terminology for this class of technologies shifted gradually from Rapid Prototyping (RP) from the 80s to Additive Manufacturing (AM) nowadays. The term “manufacturing” implies that a product is generated. Not only a product must meet tight quality constraints, but it also must be traded and applied to the advantage of the manufacturer or user. In this respect, additively manufactured parts are in competition with conventionally manufactured products, which unsurprisingly have a huge advantage in terms of price and reliability due to a long period of optimization. The return on investment for AM products is often a critical point, as capital expenditure and running costs, such as personnel and raw materials (feedstocks) are generally high and little experience exists concerning the performance and reliability of AM parts in service. This explains why the development and optimization of AM technologies is still a very vital field of research and it is difficult to provide a comprehensive picture of the state of the art, considering that innovations and equipment improvements are continuous. On the other hand, the technical challenges of AM of ceramics are more general and will likely remain the same for some time.

In order to develop a more general understanding of the technical challenges associated with AM of ceramics, it makes sense to divide the following introduction into two main categories, defined by the macroscopic physical properties and architecture of the ceramics parts generated via AM, that is: (1) porous components and (2) fully dense monolithic components. Accordingly, we will distinguish between three classes of AM technologies:

(1) technologies not capable of producing dense structures (which means, only a microstructure with residual porosity can be generated), (2) technologies capable of producing fully dense monolithic ceramic bodies with restriction in dimension, i.e., dense filaments or small structures including solid ceramic parts not larger than a few mm in diameter, and (3) technologies capable of producing fully dense monolithic ceramic bodies without restriction in dimension.

It is well known that the many AM technologies successfully applied to the manufacture of ceramics have been used to fabricate porous structures, e.g., scaffolds for biological applications, filters, lightweight structures etc. In these cases, the success of the respective technology is based on the fact that a certain amount of random and residual porosity in the solid ceramic part of the scaffold is tolerated or even desired, as it provides further functionality to the component.

The fact that, so far, a major part of the research on AM of ceramics has focused on porous structures, is due mainly to two reasons:

- (1) AM enables the production of complex shaped porous architectures with a precise control of the dimension, shape and amount of pores, which is not achievable by any other technology currently used for the fabrication of macro-porous bodies. In these cases, AM is not in competition with traditional manufacturing, but it opens up completely new fields of research and applications. Indeed, an increasing number of publications nowadays deals with the design and manufacturing of cellular and lattice structures possessing specific advantages in terms of strength-to-density ratio, stiffness, permeability or other significant properties.
- (2) Many of the AM technologies currently existing are intrinsically particularly suited for the generation of fine filigree structures. The specific reason for this statement will be discussed later, when describing the individual technologies, because it is different from case to case. However, a general observation that can be made here is that technologies that are suitable for fine porous structures have often shortcomings when scaling up to large bulk parts, and, vice-versa, technologies more suitable for the fabrication of dense parts may have difficulties in producing highly porous and fine geometries.

There are very few AM technologies on the market capable of generating fully dense monolithic ceramic bodies. AM of monolithic ceramics, enabling the components to fully retain their superior physical-chemical properties, is still a challenge and remains the most important task that needs to be solved in order to promote AM of ceramics to more than a niche technology.

In the following, the current status and performance of additive manufacturing of ceramics will be discussed. An overview of technologies for the fabrication of porous and monolithic components will be given, and particular applications will be highlighted.

Overview of Technologies

By comparing the main characteristics of the AM techniques with respect to both the properties of generated parts and processing-related aspects, this paragraph gives an overview and a comparison of the AM technologies currently available for ceramic materials, see also Fig. 1.

Table 1 summarizes some of the general characteristics of the most used AM technologies described in literature for the manufacturing of ceramic components. Indications about the quality and size of the produced parts (ability of making dense and/or monolithic parts, precision, surface quality) and cost of the production (cost of the feedstock preparation and cost of the process) are included.

Before commenting on the individual technologies, it is appropriate to qualify further the content of the columns in **Table 1**.

- (1) *Dense struts*: this term indicates technologies that can provide a dense material (that is, without any residual porosity), at least for some of the possible geometries and features that they can produce (specifically, only features possessing a small length scale or volume) and some ceramic material systems. Importantly, it is relevant to notice that there is a correlation between the use of a liquid-based feedstock and the possibility of achieving a dense microstructure in the struts (or small printed features), as opposite to solid-based and, in particular, powder-based technologies.
- (2) *Monolithic*: this term indicates technologies that are able to generate parts without residual micro-porosity, at least for some ceramic material systems, regardless of their volume and feature size, that is, e.g., wall thickness. A part with these characteristics is what we define as a “ceramic monolithic part”. Naturally, the possibility to sinter to full density is related, as for ceramic processing in general, to the composition of the feedstock (i.e., presence of sintering aids, composition of the ceramic, particle size, etc.) and on the sintering schedule and technique employed. Here, however, we consider as given that the ceramic powder could be sintered to full density (for instance if it was shaped into a tablet by cold pressing) and are interested in discussing whether it is the AM process itself that prevents this full sintering to happen in the final produced part.
- (3) *Part dimension*: this is the maximum part size that can be produced. Based on the fact that the dimension of the process area (printing envelope) can be potentially scaled-up for most technologies, it is difficult to provide precise data and trends. However, at the current state-of-the-art, it is often the case that, for dimensions outside a certain range, it becomes more convenient, for economic and technical reasons, to switch from one technology to another. These dimensional ranges are indicated as sizes from XS to XL, corresponding to 100 μm or to 1 m, respectively, as explained in the table caption.
- (4) We should also note that it is not only the dimension of the printing envelope for each AM technology that imposes a limit to the maximum part size (area or volume), but also the mechanical properties of the parts during the printing process. For instance, structures constituted by thin filaments and not supported by a liquid or powder bed can deform by their own weight during fabrication, when they're still not consolidated by sintering.
- (5) Precision and surface quality are related to the dimension and cost of the part (printing speed) to be produced. On the other hand, the surface of a part can become smoother due to the minimization of its free surface energy, if sufficient material transport can occur during fabrication or sintering, or artifacts such as steps deriving from deposited layers can be smoothed out by the presence of a liquid phase during sintering. Here, only the best state-of-the-art results achieved so far are listed. As the dimension of the part increases, the precision in many technologies can be reduced (e.g., by increasing the diameter of

Fig. 1 Schematic of AM technologies.

Table 1 Main Characteristics of additive manufacturing technologies used for ceramics

<i>Process category according to ISO/ASTM 52900</i>	<i>Technology^a</i>	<i>Feedstock (liquid or solid)</i>	<i>Dense struts (dense ceramic, but limited volume)</i>	<i>Monolithic</i>	<i>Part dimension^b (size that can be produced economically)</i>	<i>Surface (quality of parts, not of single struts)</i>	<i>Resolution</i>	<i>Cost of feedstock preparation</i>	<i>Cost of process</i>	<i>Direct vs. Indirect</i>
Binder Jetting	BJ	Solid (Powder)	No	No	M-XL	Medium	100 μm	Low	Medium	Indirect
Powder bed fusion	P-SLS	Solid (Powder)	No	No	M-L	Medium	100 μm	Low	High	Indirect
	P-SLM	Solid (Powder)	No	No	M-L	Medium	100 μm	Low	High	Indirect
Vat photopolymerization	SL/DLP	Liquid (Particle suspension)	Yes	No	XS-L	High	< 1 μm	Medium-High	Medium	Indirect
<i>Slurry-based variations of Binder Jetting and Powder bed fusion</i>	S-BJ	Liquid (Particle suspension)	Yes	Yes	M-XL	High	100 μm	Low	Medium	Indirect
	S-SLS	Liquid (Particle suspension)	Yes	Yes	M-L	High	100 μm	Low	High	Indirect
Sheet lamination	LOM	Solid (Sheet)	Yes	Yes	M-L	Medium	100 μm	Medium	Medium	Indirect

Material extrusion	DIW/Robocasting	Liquid (Particle suspension/paste)	Yes	No	S-XL	Low	10 μm	Low-Medium	Low	Direct
	FDM	Solid (Filament)	Yes	No	S-M	Low	100 μm	Medium	Low	Direct

^athe definition of the acronyms for each technology are given later in the text.^bXS = 100 μm ; S = 1 mm; M = 10 mm; L = 0.1 m; XL = 1 m.

extrusion nozzles or the thickness of deposited powder layers) in order to obtain an economical building rate. It is noteworthy that surface quality is important not only for aesthetical reasons, but also because it can influence the mechanical properties of the printed ceramic components. It is furthermore noteworthy that filament-based technologies can provide very smooth surfaces on a micro-scale level but, by fusing multiple filaments a textured surface is generated, which can significantly deviate from the surface contour of the 3D model.

- (6) The cost parameter is divided into two factors: cost related to the feedstock and cost related to the process. Cost for feedstock does not include the cost for ceramic raw materials, as this would be similar for a conventional fabrication process. Low feedstock costs imply that the material can be bought commercially and is usable with none or minimal further processing, irrespective of the cost of the specific ceramic raw material selected; this is typically the case for powders to be used in powder-based and slurry-based technologies. Medium and high cost indicates that the material requires extensive secondary processing involving expensive additives, and often has to be designed specifically for the application. An example is the ink designed for extrusion through very fine nozzles or a photocurable suspension with a high ceramic particle loading. Finally, the process cost considers depreciation of capital expenditure and operating expenses for the particular AM equipment, and costs related to necessary processing and post-processing of the final product. Machines which employ lasers, for example, are usually quite expensive and not very productive compared to equipment based on binder jetting. On the other hand, the extrusion of pastes through fine tips is typically based on a rather cheap setup, and the production rate can be adapted by changing the diameter of the tip, which makes this a low-cost process.

It is also helpful to divide the existing AM technologies into two categories: direct and indirect. Direct 3D printing means that the material is directly deposited only at the positions giving the desired shape of the final object. Indirect 3D printing means that, first a layer of material is deposited, subsequently the cross section (slice) of the part is inscribed in the layer and, after printing all layers to complete the process, the excess material surrounding the part is removed to release the final object. Inscribing can be done in several ways, each one with its own characteristics. It should be noted that, differently from metal additive manufacturing, in the case of ceramics the term “direct printing” does not indicate the production of a ready-to-use part, since no AM technologies currently exist capable of directly providing a 3D shaped, sintered body without requiring a post-forming firing step.

Already from this distinction, some general considerations concerning the potentials and drawbacks of the two approaches can be outlined:

- (1) The excess material in indirect technologies forms a support for the successive layers, enabling the generation of parts with large overhangs. Direct techniques, on the other hand, require support structures for overhangs above a certain dimension, which may be often impractical or time consuming, and furthermore need to be removed in order to obtain the precise desired shape of the final object.
- (2) Indirect technologies require the removal of the excess material in the form of powder, liquid or solid pieces of a sheet, which can be difficult or impossible for certain geometries. For example, if the excess material is a powder, it may be complicated to remove it completely from small open pores and cells. In any case, it is not possible to print any form of closed porosity, because the material inside the pores that has not been inscribed cannot be removed. The direct deposition of material, instead, does not have such geometrical limitations.
- (3) Indirect technologies have the potential to be faster, because the material is deposited in one complete layer and the layer information, that is the cross section of the part to be built, can be printed on the entire area, selectively inscribing the desired profile. Moreover, the simultaneous fabrication of multiple individual parts can be achieved. In direct technologies, instead, the material is usually deposited only in specific positions and in a sequence.
- (4) Direct technologies offer straightforward possibilities to use multi-material systems (ceramic/ceramic with functional grading, ceramic/plastic, ceramic/metal interfaces). Indirect technologies can also do this, but with much more limitations, e.g., the addition of metallic materials acting as conductor in multilayer ceramic systems is possible, but their concentration is limited (Espera *et al.*, 2019).

State-of-the-Art, Technology by Technology

By describing the main technologies developed so far, this section reviews the current state-of-the-art of AM of ceramics. Specifically, the paragraph includes a description of the ability of a particular technology to: (1) fabricate lattice structures with a designed macro-porosity and considerations about the residual micro-porosity in the parts, which might be resulting from the various fabrication technologies; (2) the possibility of producing monolithic ceramics, according to our previous definition.

Indirect AM Technologies

Powder-based 3D printing

Powder-based 3D printing includes Binder Jetting and Powder Bed Fusion. In powder-based AM technologies, a solid structure is realized by the successive deposition of layers of a flowable powder. A layer of powdered material is first spread and subsequently the corresponding layer information is selectively inscribed by e.g., local compaction or gluing; these steps are iteratively replicated

Fig. 2 (a) 3D printer for concrete, (b) powder-based 3D-printed “Nautilus” artwork model (the part is 0.8 m tall) still half embedded in the powder bed. Image courtesy of Antonino Italiano, Desamanera SRL, Italy.

until the object is completed. The layer information is defined by the corresponding cross-section of a sliced virtual 3D model of the object to be built. At the end, the part is completely embedded in a powder-bed, from which it can be easily extracted and cleaned. The technology used to inscribe the layer information depends on the specific process considered: two of the most well-known and world-wide spread processes are: “Three-dimensional printing” (3DP) and “Selective laser sintering” (SLS) (Bourell *et al.*, 1992). The milestone patent “Three-dimensional printing techniques” by Sachs *et al.* was filed in 1989 (Sachs *et al.*, 1993), while Deckard’s patent “Method and apparatus for producing parts by selective sintering” dates back to three years earlier (Deckard, 1989). Within powder-based AM technologies, powders are bound or fused to more or less dense parts, often ready to use (in particular in the case of artificial stone components, where no sintering process is required). The former method uses a printing head to selectively spread out droplets of a liquid binder (Binder Jetting), while the latter employs the energy of a focused laser beam to selectively sinter/melt a powder.

Binder jetting

In the binder jetting (BJ) process, an inkjet printing head ejects a binding liquid onto a powder bed, thus defining the cross-section of the object in that layer. Some BJ setups stabilize the powder layer by misting with water droplets to avoid disturbance of the powder by the ballistic impact of the binder droplets (Butscher *et al.*, 2013). Multiple nozzles can also be used, allowing covering a wide printing area. Printing machines with print heads consisting of hundreds up to thousands of parallel working jets are standard. Printing envelopes as large as $6 \times 6 \times 6 \text{ m}^3$ are used to fabricate ceramic objects for architectural applications based on the cold consolidation of inorganic powders (such as marble) using a hydraulic or non-hydraulic binder. In Fig. 2, an example of a large artwork piece using such an equipment is shown.

(1) Porous components

The vast majority of the research on powder-based 3D printed porous parts has been devoted to the shaping of biomedical scaffolds for tissue engineering, namely hard tissue, which are bone substitutes. Two major classes of material-binder systems have been used for this purpose: (1) the ceramic powder is bound by an organic glue, which is dissolved in a water- or solvent-based liquid and sprayed on the printing bed; alternatively, a polymer can be mixed with the ceramic powder and then used to glue the powder when in contact with a jetted solvent for the polymer. The green part has to be successively sintered at high temperatures in order to obtain the final ceramic object. (2) a reactive liquid-powder system is employed, which involves a setting reaction at low temperature. There are several examples of systems based on calcium phosphates using phosphoric acids as a binder.

An excellent review of the important scaffold parameters for this specific application, as well as of the most important processing aspects can be found in the literature (Butscher *et al.*, 2011). Typically, tissue engineering scaffolds should have pores in the range 50–1000 μm and a porosity $> 60\%$, because these characteristics are considered a requisite for successful bone ingrowth and full vascularization of the implants. Residual micro-porosity ($< \sim 10 \mu\text{m}$) in the printed part (i.e., not the designed macro-porosity) was also recognized to be important for increasing the surface area, which leads to higher protein absorption and ion exchange. It should be noted that small pores ($< \sim 500 \mu\text{m}$) cannot be printed because of resolution limits and, more importantly, because of the difficulty in removing the excess, unbound powder.

Calcium phosphate scaffolds made by BJ tend to have exactly this bimodal porosity: a designed porosity produced by BJ, in the range of $\sim 0.5\text{--}2 \text{ mm}$, and micro-porosity in the struts due to incomplete densification after binder/powder reaction and/or after sintering. In particular, sintering of the 3D-printed material to high density is hindered by the large particle size (indicatively 20–100 μm) of the powder used for printing, which is necessary in order to have a suitable level of flowability (appropriate Hausner ratio) during the deposition of the layers. Even though the flowability can be improved by granulation of a fine ($< 10 \mu\text{m}$) powder, during the heat treatment a good level of densification can be achieved within the single

granules, but only sintering necks are formed between the individual granules.

Parts made by BJ generally have a high level of residual porosity and this limits their mechanical properties. Chumnanklang *et al.* (2007) made Hydroxyapatite (HA) samples by BJ which had 20–40 vol% micro-porosity and a 3-points-bending strength < 1.5 MPa. Klammer *et al.* (2009) developed a BJ process for Brushite ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) which had a micro-porosity of 38.8 vol% and a compressive strength of 23.4 MPa, and similarly for Monetite (CaHPO_4), obtaining 43.8 vol% of micro-porosity and 15.3 MPa compressive strength. Castilho *et al.* (2015) measured the compressive strength of calcium phosphate cylinders, which reached a maximum of 23.8 MPa for a micro-porosity of 43.1 vol%.

Besides applications for tissue engineering, BJ of silicate ceramics for different applications, including art and architecture, and foundry sands are rapidly growing markets (Huson and Hoskins, 2014).

With the aim of producing parts with improved mechanical properties, fibers can be embedded in the powder bed; their size, however, cannot exceed the layer height, and their amount is limited by the flowability requirements of the powder bed. Singh *et al.* (2015) added up to 75%vol of SiC fibers ($\sim 70 \mu\text{m}$ length) to a SiC powder bed in order to fabricate demonstrators for turbine engine component applications. Fibers were well distributed, showed no preferred orientation on the horizontal plane and angles as much as 45° in the vertical plane.

(2) Monolithic components

BJ is very well suited to generate porous ceramic structures. Still, a major issue, hampering a completely autonomous production of parts and even restricting the freedom of design by means of these technologies, is the low density and stability of the parts during the building process, which is a direct result of the low powder packing in the powder-bed. The powder bed surrounding the part has an essential role, since it should support the structure during building, until it's ready for removal. Furthermore, powders with appreciable flowability for the deposition of thin layers are in a particle size range $> 20 \mu\text{m}$, which generally does not provide sufficient sintering activity to form dense ceramics. One straightforward approach to increase the density of the powder bed and to use more fine powders is the deposition of ceramic slurries instead of dry powders. This strategy will be introduced in a following section. Another approach is the gas flow assisted powder deposition (Zocca *et al.*, 2014). While the first approach results in powder beds with powder packing densities $> 55\%$ TD, and thus sufficient for a full densification in subsequent sintering steps, the latter has just shown its potential for the deposition of fine powders ($< 20 \mu\text{m}$ particle size) with appreciable packing densities. The low powder packing density has two major causes: the particle shape, which is generally far from spherical, and the tendency to form agglomerates. Also, particle charging due to the low electrical conductivity of ceramic materials might contribute to low packing densities.

Even though, as discussed above, the microstructure of parts obtained by BJ usually contains a high amount of residual porosity, some authors achieved high density values after the heat treatment process. Three different approaches have been mainly investigated with this aim.

The first approach consists in modifying the composition of the ceramic material in order to enhance the sintering, by addition of dopants or of a viscous liquid-forming phase. Fielding *et al.* (2012), for example, obtained 95% density when adding ZnO and SiO_2 to tricalcium phosphate (TCP), while Suwanprateeb *et al.* (2009) took advantage of liquid phase sintering producing a 97.5% dense HA + HA/woollastonite glass-ceramic composite.

The second approach is the infiltration of a porous preform produced by BJ. Melcher *et al.* (2006) used BJ to print alumina preforms which had a porosity of 36% after sintering and infiltrated them with Cu/Cu₂O. The resulting $\text{Al}_2\text{O}_3/\text{Cu}/\text{CuO}$ material had a flexural strength of 236 MPa and fracture toughness of $5.5 \text{ MPa m}^{1/2}$ thanks to the crack bridging mechanism of the metallic phase. A similar process was followed to infiltrate alumina preforms with glass (Zhang *et al.*, 2009).

Another interesting material system achievable with this approach is the formation of RBSiC ceramics (reaction-bonded silicon carbide). In a first example, Fu *et al.* (2013) printed by BJ a mixture of Si, SiC and dextrin. Successive infiltration with a liquid silicone resin and pyrolysis at 1000°C in nitrogen yielded carbon from the dextrin and an amorphous SiOC residue from the silicone resin. Infiltration of liquid silicon at 1500°C in vacuum finally lead to the RBSiC material, also designated as SiSiC. Moon *et al.* (2001), instead, printed by BJ a carbon preform which had 48% open porosity, by using a binder based on furfuryl resin. Following infiltration of Si at 1450°C in nitrogen led to the desired RBSiC composite. It is interesting to notice that in this latter example part of the carbon was derived from the polymeric binder, and this allowed the generation of functionally graded parts by varying the dosage of carbon-yielding binder and thus controlling the amount of SiC formed. Fig. 3 shows a voluminous SiSiC part, which has been obtained by BJ of SiC powders followed by Si infiltration during sintering.

The first two approaches may be however difficult to apply to pure technical ceramics, such as alumina or silicon nitride. A third approach has been developed which consists of cold isostatic pressing (CIP) or warm isostatic pressing (WIP) the green body printed by BJ, before sintering. Yoo *et al.* (1993) obtained almost dense parts (99.2% relative density) by applying WIP to alumina parts (with MgO dopant) which had a flexural strength of 324 MPa after sintering. This method has been applied also to other ceramic systems, such as Ti_3SiC_2 , yielding almost dense microstructures, but it poses geometrical limitations when applied to complex geometries, such as parts with internal cavities (Sun *et al.*, 2003).

Concluding, BJ is very attractive because it has almost no limitation regarding the parts geometry (except for closed porosity) and dimension; however, it is potentially able to produce ceramic monolithic parts only for specific material systems, typically involving post-printing infiltration with metals or semimetals.

Fig. 3 Complex structure made from RBSiC by the BJ process with dimensions: $880 \times 750 \times 300$ mm, volume 9.000 cm^3 . Image courtesy of Schunk Ingenieurkeramik GmbH, Germany.

Powder bed fusion

The powder bed fusion process comprises both Selective Laser Sintering (SLS) and Selective Laser Melting (SLM). It works similarly to BJ, with the difference that the cross sections of the part to be built are inscribed by means of a laser beam. The local densification of the powders can be obtained by directly sintering the ceramic powder, or by mixing the powder with a binder phase (inorganic or, more often, polymeric) which is then melted by the laser light. Direct laser sintering of ceramics is complicated by the poor resistance of this class of materials to thermal shock. Furthermore, the short interaction time between laser and powder limits material diffusion, leading to poor sintering (Kruth *et al.*, 2007; Regenfuß *et al.*, 2007). Binders within the powder which can be thermally activated, on the other hand, have been successfully used to shape porous ceramic parts, for applications and with results similar to those produced by BJ (Juste *et al.*, 2014).

(1) Porous components

Kolan *et al.* (2011) produced bioglass scaffolds with 50% porosity and pores in the range $300\text{--}800 \mu\text{m}$ by using an acrylic binder, followed by sintering at $675\text{--}695^\circ\text{C}$. Liu *et al.* (2012) deposited layers of a slurry made of hydroxyapatite powder and silica sol, exploiting the gelling of silica as binding mechanism, followed by sintering at 1200°C . The produced scaffolds had pores in the range $750\text{--}1050 \mu\text{m}$ and a porosity of 25%–32%.

(2) Monolithic components

Similarly to BJ, there are some rare examples in which dense monolithic ceramics have been obtained by SLS by infiltration with metals or semimetals after printing a porous ceramic preform. One of the early results concerns the generation of Si/SiC parts. Within the SLS process, SiC particles are glued together as a result of the formation of SiO_2 in oxidizing atmospheres, that is, ambient air. The highly porous parts have been used as preforms for the silicon infiltration (Löschau *et al.*, 2000).

More recent work concentrates on selective laser melting, where the formation of a liquid phase ensures rapid densification (Wilkes *et al.*, 2013). The use of dense alumina and zirconia spherical particles ($30 \mu\text{m}$) as feedstock results in a high packing density of the particles in the powder bed. Preheating of the powder bed to a temperature of at least 1600°C reduces the thermal shock within the part to be built. Alumina-Zirconia eutectic mixtures reduce the melting temperature of the powder bed to about 1860°C . With this approach, dense ceramic parts with remarkable mechanical properties could be generated via SLM. Nonetheless, crack formation within the ceramic bodies could not be avoided completely, and an uncontrolled infiltration of the preheated powder bed by the liquid phase formed within the laser spot results in an ill-defined outer contour of the parts generated.

Exploitation of viscous flow drives the fabrication of soda lime silica glass components via SLM (Datsiou *et al.*, 2019). Complex multilayer structures with good resolution were fabricated after optimization of laser processing parameters; however, the built parts showed no transparency but an opaque appearance which can be jointly attributed to residual porosity (above 11%) and to the presence of partially fused powder particles on the outer surface of the parts, which is typical for powder bed processes.

Even though there is currently no strategy in sight which would allow for the formation of dense monolithic ceramic parts via SLM, with precise contour and properties similar to conventional manufactured ceramic parts, the laser based technologies

SLS and SLM are the only processes which could potentially deliver ready to use ceramic parts from ceramic materials that require sintering.

Vat photopolymerization

This category includes Stereolithography, Digital Light Processing and Two-Photon Polymerization.

The vat polymerization technique is based on the photopolymerization of a liquid organic resin filled with ceramic particles, in a layer-by-layer fashion similarly to the other indirect AM technologies. Typical compositions for the slurry include a monomer solution, a photo-initiator and additives for the dispersion of the ceramic powder, with a concentration of 40–60 vol%. The formulation of stable suspensions requires a careful use of appropriate additives, and matching of the refractive index of powders and liquid medium is necessary for achieving high resolutions (Zhou *et al.*, 2010; Chartier *et al.*, 2008).

Stereolithography (SL) uses a laser beam to selectively and sequentially irradiate the liquid forming each layer, while Digital Light Processing (DLP) projects the entire layer image on the liquid by means of Micro-Mirror-Arrays (MMA). Differences among the techniques include equipment, cost, speed of manufacturing, resolution and surface quality (notably, DLP generates the so-called “stair stepping effect”, leading to unsmooth features on inclined lines). MMA’s or galvanometer mirror scanners are commonly used to project the light. The MMA technology enables a faster processing while scanners can provide higher lateral resolution; hence sometimes both technologies are combined.

Contrary to powder-based AM, in vat polymerization the material surrounding the part is liquid and therefore it is unable to provide any support; for this reason, depending on the specific geometry of the part, support structures are often built together with the part, requiring subsequent removal. Due to the high green densities and the use of fine ceramic particles, vat polymerization permits the production of almost dense ceramic parts after sintering.

Different technical solutions exist on the market for the vat polymerization process, depending on the position of the light source with respect to the vat, and the way in which the new slurry layer to be photopolymerized is provided. In the bottom-up approach, the light source is positioned below the vat containing the photopolymerizable slurry, while in the top-down approach the opposite occurs. “Top” and “bottom”, in this context, refers to the position of the building platform relative to the part and the light source: bottom-up, the building platform moves up at each layer while the part is built hanging on the platform with the light source below, top-down, the building platform moves down at each layer while the part is built standing on the platform with the light source above. Fig. 1 shows the top-down approach. Because of the way in which the new layer of unpolymerized slurry forms on the already polymerized part, the top-down approach shows some restrictions in terms of the printing of components possessing large cross sections parallel to the vat surface, while the bottom-up method has some limitations in terms of the length/width ratio of the component being fabricated (Santoliquido *et al.*, 2019). Continuous or semi-continuous printing is possible with the top-down approach, with building speeds up to a few mm/min.

Some equipment adopts an approach in which the part built is not fully immersed in the liquid feedstock, but mounted upside down (bottom-up process) on the building platform and dipped in a thin slurry layer deposited on a glass plate (Homa and Schwentenwein, 2014). The striking advantage of this strategy is the small amount of slurry required for building the part, and that different approaches can be developed for spreading each new layer of suspension (such as the use of a doctor blade), enabling the use of highly concentrated slurries with high viscosity.

Densities of parts manufactured by vat photopolymerization after debinding are typically around 50%–55% TD. The powder compact after debinding is sometimes denoted as “brown” compact. Due to the fact that very fine powders can be processed by this technique, it is possible to achieve densities exceeding 99% TD after sintering.

The binding phase is not always completely removed; if the debinding step is performed under inert atmosphere, pyrolyzed carbon remains within the structure, forming a ceramic matrix composite with electrical conductivity and enhanced microporosity suitable for photochemical applications (Mei *et al.*, 2019).

Two-photon polymerization (2PP) is a novel nano-stereolithography technique allowing cross-linking of a polymer with a resolution down to 200 nm. As this technology generally writes the structures directly in the volume of the resin with an optical setup of extremely short focal length comparable to optical microscopes, scattering of the light on the ceramic particles is an issue which has to be solved. One approach is the use of a photocurable preceramic polymer instead of ceramic powders (Brigo *et al.*, 2018). Another approach suggests using ceramic powders with a particle size about 10 times smaller than the wavelength of the light employed for photocuring. Particles of this size are no longer able to scatter the light and two-photon polymerization could be used to generate ceramic powder compacts with extremely small feature sizes. However, all parts need to be fabricated attached to a solid substrate, whose removal can be complicated.

(1) Porous components

The utilization of the vat photopolymerization technology was investigated for the generation of porous ceramics for various applications, taking advantage of the high precision that this technology provides and the possibility of obtaining dense struts. In all cases, the struts density ranged between 95% and 98% TD. Furthermore, complex lattice structures can be rather easily manufactured.

(2) Monolithic components

Generally, it is possible to produce dense monolithic ceramic parts via vat photopolymerization, because powder compacts with powder packing densities higher than 55% can be generated. The only restriction is imposed by the debinding step, which is required to remove the binding additives from the green compacts before sintering. The thermally activated

debinding steadily transforms the binder into gaseous species and is one of the most critical steps in the vat photopolymerization process due to the possible formation of defects in the brown compact. Since thermal debinding takes place in the volume of the part and dissociation and combustion products must leave the bulk by diffusion, the heating process has to be carried out very slowly keeping the pressure inside the part below a critical threshold avoiding the formation of cracks and voids. On the other hand, there already exists a vast expertise on the thermal-, catalytic- and solvent-based debinding of ceramic green compacts, from injection molding of ceramics. Injection molding also uses pastes with high organic content, as binders, plasticizers, dispersants and lubricants, to produce parts with high complexity. Thus, regarding the production of dense monolithic parts, a clear restriction of the vat photopolymerization process is, similarly to injection molding, the maximum volume or wall thickness of the ceramic green body at which debinding can be achieved in a reasonable time. At wall thicknesses of about 1 cm, debinding already requires a thermal treatment over a time period of several days.

The high packing densities achievable with vat photopolymerization processes make them appealing for the fabrication of glass components. Full density, however, is just one of the requirements in order to produce transparent parts; in fact, the starting powder also needs to be very fine (about 10 times smaller than the wavelength). Transparent fused silica glass components were produced by DLP from a colloidal suspension of fused silica particles with a mean diameter of 40 nm (Kotz *et al.*, 2017). By doping the ink with metal salts, colored glass components were also demonstrated.

Similar results were obtained by Cooperstein *et al.* (2018) using a different approach, i.e., the development of a silica glass component via a sol-gel route. The ink contains no particles and is based on a hybrid ceramic precursor, 3-acryloxypropyl trimethoxysilane (APTMS), that can crosslink both via photopolymerization and via sol – gel process. The ink is first printed via DLP and then aged and converted from a gel to a xerogel and then to a transparent silica glass component.

Slurry-based BJ (S-BJ) and slurry-based SLS (S-SLS)

S-BJ and S-SLS are technologies which are a logic extension of powder-based technologies. Instead of spreading a dry powder into thin layers, a ceramic slurry or slip is used, in order to increase the powder packing density in the powder bed. Each layer is inscribed either by using a multi-jet printhead (S-BJ) or by using a laser beam (S-SLS).

In S-BJ and S-SLS, a liquid suspension of ceramic particles is spread as a thin layer comparable to tape casting, while within this layer a cast is formed comparable to slip casting. In the slip casting process, the slip is brought into contact with a porous body, the casting mold. When a liquid is wetting a porous body, capillary forces draw the liquid phase of the suspension into the porous mold. The particles start to form a powder compact, the cast, at the molds surface. The cast formation kinetics obeys a square-root-of-time law, by depositing individual particles from the suspension to the surface of the mold. In case of the Layerwise Slurry Deposition (LSD) process, the mold is formed by the previously deposited and dried layers (Mühler *et al.*, 2015). Slip casting results in the formation of powder compacts with densities potentially exceeding 60% TD. Furthermore, due to the free settling of the powder particles from the suspension, no obvious interface is formed between individual layers.

In the powder-based BJ and SLS processes, the part built is easily released from the powder bed, but this is not the case for the slurry-based process. After deposition of all layers required for building up the desired geometry, the laser sintered or printed body is embedded in the powder bed which now is a block of densely packed particles (Mühler *et al.*, 2015). For the release of the part, the powder compact must be dissolved by a solvent. In case water-based slurries are used for the layer deposition, water can act as a solvent for the powder bed.

For the manufacture of a powder compact with properties comparable to those produced by classical powder processing, S-BJ has a high potential (Zocca *et al.*, 2019). By the use of small amounts of organic or inorganic binders provided by a printing head, the particles in the densely packed powder bed are locally glued together, and compacts generated by this technology don't require any additional treatment prior to sintering. The laser treatment in S-SLS, however, will affect the microstructure of the powder compact typically in a direction which is not favorable for the production of advanced ceramic.

(1) Porous components

Like powder-based 3D printing, including Binder Jetting and Powder Bed Fusion, the ability of generating porous structures by slurry based 3D printing primarily depends on the volumetric resolution of the technology. As very fine particles with high sintering activity can be processed, which potentially sinter to dense ceramics, structures with designed porosity and dense struts can be obtained. Also, it is possible to use coarse powders for obtaining a random micro-porosity by incomplete sintering, similarly to binder jetting using dry powders.

(2) Monolithic components

S-BJ is particularly well suited for the generation of monolithic ceramic parts (Fig. 4). Fine particles enable a high sintering activity of the powder compacts printed and low binder contents facilitates a rapid debinding without generation of defects. The laser based S-SLS process, however, is not taking advantage of these features, as the inhomogeneous heat treatment by the local laser irradiation is resulting in defect structures, such as cracks and bubbles, which cannot be removed in a subsequent sintering step.

Laminated object manufacturing (LOM)

Originally known as Layered Laminated Manufacturing (LLM), later on commercialized under the trade names Laminated Object Manufacturing (LOM) by Helysis or CerLAM and MetLAM by Javelin 3D, this AM process builds 3D parts by the lamination of

Fig. 4 Release of a turbine made of SiC by employing the Layerwise Slurry Deposition (LSD) technology in combination with binder jetting. (a) powder bed, formed by 120 layers with a thickness of 100 μm , containing the turbine; (b) turbine partially released from the powder bed; (c) turbine green body.

paper, tapes or similar shapes at low-medium temperature and pressure (Gomes *et al.*, 2008). LOM has been considered as an alternative for the lamination of green ceramic tapes into 3D dense or semi-dense parts.

The main advantage of this technique is the possibility of producing laminates directly from green tapes, which in turn are produced by established technologies, such as extrusion or tape casting. Compared to some conventional manufacturing processes such as injection molding, extrusion, or roll pressing, LOM parts exhibit moderate values of flexural strength at relatively high porosities. Values of mechanical strength for silicon nitride parts obtained by LOM of $\sim 475 \pm 34$ MPa have been reported (Liu *et al.*, 2015), which is comparable to silicon nitride ceramics prepared by pressureless sintering (Penas *et al.*, 2001) and higher than for components fabricated by gel casting (54.5 ± 2.3 MPa) (Wang *et al.*, 2013).

The main drawbacks of this technology, as in most lamination processes, are related with the quality of the interfaces between tapes and the presence of defects. Common issues being reported are delamination, interfacial porosities and differential shrinkage (Gomes *et al.*, 2008, 2011).

(1) Porous components

The LOM process uses tapes or papers as feedstock, which needs to be shredded in small pieces layer by layer by means of a knife or laser. These pieces do not provide flowability like ceramic powders. Hence, the removal of the excessive material embedding the part is one major concern. LOM is basically not the right choice to build up filigree structures or structures with complex designed porosity. On the other hand, random porosity can be obtained by incomplete sintering of coarse-grained powders or by the burn out of sacrificial organic fillers added to the tapes.

(2) Monolithic components

In principle with LOM dense monolithic parts can be generated, since the ceramic tapes can be very well optimized regarding sintering properties. One concern is, however, the interfaces between laminated tapes which are prone to defects. Nonetheless, ceramics revealing properties comparable to conventionally manufactured ones can be obtained.

Direct AM Technologies

Material jetting

Material jetting, or inkjet printing (IP) is a technology which uses a ceramic suspension to build up structures by the successive deposition of individual drops provided by a printing head. The ceramic suspension, or ink, consists of ceramic particles (typically > 20 vol%) dispersed in a liquid carrier containing different additives to stabilize the suspension, adjusts its viscosity and surface tension, and to control the spreading and drying of the deposited droplets (Özkol *et al.*, 2010; Teng and Edirisinghe, 1998). As liquid carrier, water or organic liquids can be used, depending on the specific requirements of the printing head. In order to ensure that ceramic particles can be fed as a suspension through the individual deposition nozzles of the printing head, their size (d_{50}) is typically kept in the sub-micrometer range at a narrow particle size distribution (Derby, 2011). Different to powder based 3D printing, IP builds up structures directly from the material provided by the ink. IP technology is capable to generate complex structures with a high powder packing density, as it uses ceramic suspensions. Together with a good sintering activity of the generated green parts, ensured by the use of submicron powders, IP can provide parts from oxide and non-oxide ceramics with appreciable mechanical properties. Furthermore, due to the small volume (picoliter) of the individual droplets provided by the printing head, the generation of structures with well controllable material gradients is possible in multi material IP setups (Wätjen *et al.*, 2014). The printing of complex shaped structures with overhangs and undercuts can be realized by printing support structures with an ink providing a sacrificial material (e.g., carbon black), which is conveniently removed during firing in oxidizing conditions. Currently, IP of ceramic materials is industrially developed for the fabrication of 2D components (e.g., printed electronics) (Tomov *et al.*, 2010) as well as 3D parts.

A relatively new technology, similar to IP, is the direct deposition of wax droplets filled with ceramics (Thermoplastic 3D Printing). This technology generally uses different print heads than those of most IP technologies, but it shares many features

with IP especially the capability to generate multi material components (Scheithauer *et al.*, 2014). The building rates are, however, significantly higher than IP because of the larger droplets formed by the wax deposition process. Dewaxing of the printed powder compacts, on the other hand, requires an additional thermal treatment before sintering to dense ceramic bodies.

Material extrusion

This category comprises different technologies, in which a viscous liquid is passed through a nozzle and is deposited layer-by-layer following a continuous path. The technologies *Direct ink writing* and *Fused Deposition Modelling* are described in the following.

Direct ink writing

Direct ink writing (DIW), also known as Robocasting, is based on the extrusion (using a syringe or a proper screw extruder) of a ceramic paste (ink) of suitable rheology in the form of a filament. The control of the rheological properties of the filament is essential to prevent deformation of the part after extrusion and sagging of the filaments, especially when the geometry includes spanning features as in most porous components. The fluid should show an initial yield stress and have a viscosity which decreases with increasing the shear rate (Herschel-Bulkley fluid). The technique was originally patented and developed by Cesarano and Calvert (2000) at the Sandia National Laboratories in the USA under the name of "Robocasting". In Robocasting, a ceramic suspension with a high solid loading undergoes a transformation from a pseudoplastic to a dilatant behavior when extruded in air, triggered by minimal drying of the slurry. Drying in air, however, limits the minimum diameter of the printing nozzle to about 500 μm , otherwise clogging is experienced. In order to overcome these issues, inks have been developed which have a reversible gel transformation and are deposited in a non-wetting (often oil) bath. Briefly, they behave like a viscous gel when loaded in the printing head, but as they are extruded the shear stress breaks the gel structure and the viscosity decreases of several orders of magnitude. After extrusion, the fluid undergoes a quick gelation increasing again the viscosity to a level before shearing which prevents deformation of the filament. This behavior can be achieved by controlled flocculation of a ceramic suspension (e.g., by a change in pH, ionic strength of the solvent, addition of polyelectrolytes) to form a gel (Lewis *et al.*, 2006), or by using gelling additives, for example by using an inverse thermo-reversible gel (Saiz *et al.*, 2011). More recently, Eqtesadi *et al.* (2014) showed that the use of polyelectrolytes and the control of the pH may be a difficult approach for bioglass inks, because of the glass dissolution and leaching of ions in water. In this case, carboxymethyl cellulose was successfully used as an additive to disperse the glass powder and to obtain a suitable rheological behavior. Another possibility is the formulation of a ceramic ink containing a polymeric binder and plasticizer (e.g., PVB and PEG), which can be added up to 23 wt% (relative to the ceramic phase). For fine lattice structures, defects generated by debinding were not reported. These variations of Robocasting have been mostly denominated "direct ink writing" (DIW) technologies.

Typical nozzle sizes are in the range 100–1000 μm and, after drying, the material has a high green density (up to 60%), which allows to achieve an almost complete densification upon sintering. The combination of fine and dense filaments makes the technology particularly attractive for the production of components suitable for several applications, based on structural and functional ceramics.

In all material extrusion processes, the ink flow through the nozzle is associated with shear stresses reaching their maximum at the tip; when directional fillers, such as platelets or fibers, are embedded in the inks, the stress field will align them in the flow direction. Exploiting this phenomenon, Feilden *et al.* (2017) fabricated composites with alumina nanoplatelets aligned along the printing direction and demonstrated that such architecture can be used to direct crack propagation (twisting and tilting) at the microscopic level.

Alignment of short fibers inside a ceramic matrix also shows great potential for anisotropic, localized reinforcement designed and informed by the CAD file. Carbon fibers (100 μm length) were embedded in a preceramic polymer ink yielding SiOC matrix after pyrolysis under inert atmosphere (Franchin *et al.*, 2017a). The composite material also comprised SiC powder in order to hinder its shrinkage. The flexural behavior of single filaments was studied in a later work, showing fiber alignment and pull-out mechanisms at the fracture surface; the filaments could deflect consistently before breaking, and showed improved toughness and graceful failure (Franchin *et al.*, 2018).

(1) Porous components

The direct deposition of ceramic inks is arguably the most used AM technology for the generation of porous structures. Stuecker *et al.* (2003) reported the production of mullite porous meshes with 100–1000 μm pore sizes and 225–1000 μm filament diameter, obtaining a relative green strut density of 55% and a sintered strut density of 96%. Smay *et al.* (2002) produced lead zirconate titanate (PZT) periodic lattices with a diameter of 200–400 μm , consisting of linear or radial arrays. The rod spacing varied from 300 to 1200 μm , thus determining spanning features. The same material system has been used later to produce PZT arrays for ultrasonic sensing applications in the 2–30 MHz frequency range (Smay, 2004). These arrays were densified and infiltrated with an epoxy resin to fabricate PZT–polymer composites with 2–2 connectivity. Smay *et al.* (2007) also demonstrated the DIW of ternary mixtures of BaTiO₃, BaZrO₃, SrTiO₃ by using a nozzle mixer. Furthermore, they produced Ni–BaTiO₃ metal-ceramic multilayer structures by using an array of single nozzles, demonstrating that by this technique it is possible to fabricate graded and multi-material porous structures. The use of geopolymer inks enabled the fabrication of porous inorganic structures suitable for filtration and other applications (Franchin *et al.*, 2017b).

For this fabrication method too, a major part of the research has focused on the shaping of bioceramics into porous scaffolds. Genet *et al.* (2013) modeled the compressive strength of HA porous scaffolds based on a Weibull approach. They

Fig. 5 Direct ink writing with geopolymer-based inks (example composition reported in Franchin *et al.*): (a) fabrication of a twisted lattice structure with a 0.8 mm nozzle tip; (b) porous lattice structure with 45° alignment (for filtration purposes); (c) solid object (the stacking of different layers is clearly visible on the surface). Geopolymeric components consolidate at room temperature and do not require a following sintering step.

could fit well experimental data, showing a decrease in compressive strength upon increasing rod spacing (i.e., porosity), keeping a constant rod diameter. Interestingly, even when the rod spacing (400–985 μm) and diameter (200–610 μm) were varied in order to keep the porosity constant (45 vol%), there was almost a four folds decrease in strength as the rod diameter increased. Franco *et al.* (2010) formulated an ink containing a thermo-reversible gel which had low viscosity at low extrusion temperature and underwent a quick gelation following deposition in a warm (60°C) oil bath. They produced HA, TCP and biphasic calcium phosphate (BCP) scaffolds and found that the micro-porosity in the struts varied in a wide range of 5%–40% as the content of thermo-reversible gel was increased, and the bending strength decreased accordingly from ~ 25 MPa to ~ 2 MPa.

Miranda *et al.* (2007, 2008) produced HA scaffolds which had 39% total porosity and 15% strut micro-porosity and studied their fracture modes under uniaxial compression. These scaffolds had a compressive strength of ~ 50 MPa, and in a similar work it was shown that this value was doubled after two weeks immersion in simulated body fluid (SBF). Fu *et al.* (2011) produced particularly strong bioglass scaffolds with completely dense rods of 100 μm diameter and a total porosity of 60%. These scaffolds had unidirectional pores and, as expected, anisotropic mechanical properties, reaching 136 MPa in the channel direction and 55 MPa in the perpendicular direction. The dependence of the compressive strength on the porosity in the 60%–80% range was also in good agreement with the Gibson-Ashby model for cellular ceramics.

It is worth noting, however, that by DIW it is also possible to obtain scaffolds with porous struts by adding a porogen to the ceramic paste (Dellinger *et al.*, 2007). They added PMMA microspheres to the ink and produced scaffolds with three levels of porosity: macropores (100–600 μm) were designed by controlling the arrangement and spacing between rods of HA; micropores (1–30 μm) were produced within the rods by including PMMA microspheres; submicron pores (less than 1 μm) were the result of incomplete sintering. Hierarchical porous ceramics with tunable pore sizes across three different length scales were also produced using inks in the form of particle-stabilized emulsions and foams, that were sufficiently stable to resist coalescence during printing (Minas *et al.*, 2016).

A further degree of versatility for this 3D printing technique can be achieved when using extrusion nozzles which enable the fabrication of cross-sections different from the standard circular one, such as square, hexagonal and other complex micron-sized geometries, or even hollow filaments (Schlordt *et al.*, 2013).

Scaffolds produced by DIW generally possess better mechanical properties compared to scaffolds produced by powder-based technologies. It seems reasonable to correlate this observation with the micro-porosity in the scaffold struts: even though this value depends also on the specific material system used, there is a clear influence of the process, which can be found when examining the properties of parts shaped without designed porosity. Parts produced by BJ generally have a high level of residual micro-porosity, while parts produced by liquid-based processes can be almost completely dense after sintering.

(2) Monolithic components

Monolithic components can certainly be fabricated with this AM technology; however, one has to be aware that the surface of printed components will show a distinct roughness formed by the individual filaments and, given the rheology of the ink, the cross-section can contain voids between adjacent circular filaments. A non-isotropic mechanical behavior can also be expected, due to the preferred orientation of the filaments within the printed structure, and therefore the parts do not typically perform as the homogeneous ceramic monoliths produced by traditional ceramic technologies.

As an example, which illustrates the capabilities of DIW to generate lattice structures and dense ceramic parts, in Fig. 5 images of a zirconia lattice structure during printing (Fig. 5(a)) and after printing (Fig. 5(b)) and a dense part before sintering (Fig. 5(c)) are shown. Note that, the dense part shows a distinct corrugation of the surface resulting from the deposition of individual filaments.

Similar to DLP, with DIW it is possible to produce transparent glass components from suspensions of nano-sized silica particles (Nguyen *et al.*, 2017). Rheology of the inks can be tailored for spanning features or for seamless interfaces in monolithic parts. Nguyen *et al.* also demonstrated the fabrication of multi-composition glass parts using a second dispensing unit filled with a gold nanoparticle-doped silica ink.

A sol-gel approach is also applicable to DIW and seems to be a promising route for transparent multi-component glass parts. The sol-gel chemistry can be tuned for both rheology control and for preparing a wide range of glass-forming metal oxide feedstocks. Destino *et al.* (2018) demonstrated this approach by fabricating SiO₂ and SiO₂-TiO₂ glass monoliths of optical quality from Si- and Ti-alkoxide derived inks.

Fused deposition modeling

In parallel with the extrusion of ceramic pastes, and in analogy with the most popular process used for the production of polymeric components, another approach has been developed: the fused deposition modeling of ceramics (FDM). This technique is based on the use of a flexible filament comprised of a significant amount of polymer (usually, a wax) and a ceramic powder, which is melted during the extrusion because the printing head is heated and solidifies by cooling immediately after in order to prevent deformation of the filament. Ideally, in analogy with FDM of conventional polymers, a continuous filament should be produced and fed to the printing head, but it is very difficult to prepare a filament with a high loading of ceramic particles that is not brittle and can be collected in spools to be continuously supplied to the printing head. After printing, the polymeric binder is burnt out and the ceramic phase is sintered. Grida and Evans (2003) extruded a mixture of 55 vol% zirconia in wax through nozzles with diameter between 76 and 510 µm. The minimum diameter of the nozzle is similar in FDM and in DIW (0.1 mm). The same authors observed that fine log-pile structures could be produced with a 100 µm diameter filament but not with a 76 µm filament. The reason was that the latter filament solidified too quickly in ambient air. Park *et al.* instead extruded 40 wt% HA mixed with PCL at 100°C through nozzles with diameter 400–600 µm (Park *et al.*, 2011). They also measured the influence of the deposition pattern on the compressive modulus and they studied the attachment and proliferation of osteoblast-like cells.

Gorjan *et al.* (2017, 2019) investigated the processing of piezocomposites and mullite structures by FDM. At Rutgers University (New Jersey, USA), an FDM apparatus has been developed which is able to deposit up to four different materials in the same layers, employing four deposition units (Jafari *et al.*, 2000). Jafari *et al.*, in the same work also produced a multilayer piezoelectric component transducer composed of soft and hard PZT, and they suggested the fabrication of components based even more complex composite materials, for example through the simultaneous deposition of ceramic, metal, electrode and fugitive phases.

The printing envelope for current FDM printers can be rather large, and robot-based systems can enable free-form fabrication, due to the fast cooling of the molten filament on exiting the nozzle.

Similarly to DIW, FDM is well suited for the manufacture of scaffolds. The presence of a large amount of organic binder makes however processing of monolithic components cumbersome, and the exothermic decomposition reaction can lead to the generation of microdefects decreasing the strength of the part.

We should also mention that it is possible to couple filament-based AM technologies with computer numerical control (CNC) machining that, at the same time, shapes the object and produces a good surface finish. In any case, the surface texture is not always problematic, but since it is a specific characteristic of these extrusion-based technologies, it has to be taken into account when designing a component. Concluding, extrusion-based AM technologies are particularly suitable for producing arrays of separate struts but are not yet able to produce proper monolithic ceramics, at least according to a most general definition.

Such limitation does not exist when the filament or feedstock does not involve any organic binder: this is the case with glass, which can be molten and deposited similarly to thermoplastic polymers, only at higher temperature (~1000°C, depending on glass composition). In 2015, Israeli company Micron3DP demonstrated extrusion of soda lime and borosilicate glass fibers thanks to their proprietary high temperature heated head. They were able to produce components of few centimeters, but were limited to simple shapes and low resolutions and were experiencing issues in terms of thermal shock of the printed components. In the same year, researchers at Massachusetts Institute of Technology (MIT) revealed the first prototype of a glass printer composed of high temperature modular elements able to process glass from the melting stage to the final, annealed product (Klein *et al.*, 2015). The printer operates at a different scale, with a 10 mm diameter nozzle and a build volume of 250 × 250 × 300 mm³. For this reason, the feedstock is not a fiber; it is either glass nuggets or (for higher production volumes) molten glass collected from a furnace and directly poured into the crucible. The addition of an annealing chamber, in which glass is deposited and slowly cooled down after printing, allows releasing tension and avoids thermal shock.

Both Micron3DP and MIT developed their systems over the following years. The first one developed an improved printer implementing an annealing chamber as well as continuous filament feeding (Bracha and Gal-Or, 2018a, b, c) and used it to fabricate microfluidic systems (Gal-Or *et al.*, 2019). The group at MIT improved and scaled up their platform towards and industrial scale glass printer and used it for the fabrication of architectural scale (3 m tall) structures (Inamura *et al.*, 2018); their spin-off, Lios, is currently taking on the system development and using it to create new design installations and products, starting with lighting.

Negative AM Technologies

While most current research focuses on the use of AM technologies that can directly produce ceramic components, negative replica methods are sometimes attractive because they can overcome at least some of the limitations in the physical, functional and geometrical characteristics of components produced. In this approach, a sacrificial polymeric mold is fabricated by AM and then, generally, impregnated with a ceramic slurry. After polymer removal (by decomposition, burn-out or dissolution) and sintering, a ceramic component is obtained. The fabrication of molds by AM adds a step to the processing route, but it allows for the use of AM technologies typical of polymeric materials, some of which are at a greater stage of development compared to AM of ceramics, implying an easier process and often better resolution and surface quality. We should also note that negative replica methods have been long used for the casting of metals, by producing using AM either a ceramic mold or a wax pattern for the investment casting process (Chhabra and Singh, 2011).

Almost every AM technology can be used to fabricate the mold. Detsch *et al.* (2008) used a printer which deposited a wax dropwise and impregnated the wax mold with a HA slurry. They also replicated a similar geometry by Robocasting, obtaining scaffolds with 44% porosity in the case of negative AM and 37% for the sample produced by Robocasting. In both cases, the pore size and strut diameter were 300 μm and 500 μm respectively, and the strut relative density reached 96% after sintering, indicating the two approaches are fully interchangeable. A similar fabrication route was followed to produce epoxy molds by SL to generate $\text{TiO}_2/\text{SiO}_2$ diamond structures for application as photonic crystals (Yin *et al.*, 2004). SL has also been used to produce resin molds for HA scaffolds with 50% geometrical porosity; in this case, a gel-casting technique was employed to improve the strength of the ceramic green body (Woesz *et al.*, 2005). Bose *et al.* (2003) produced molds by fused deposition modeling (FDM) of a commercial thermoplastic polymer, which were subsequently impregnated with TCP or Al_2O_3 slurries in order to produce porous scaffolds and investigated the influence of the pore size (300–500 μm) and porosity (25%–45%) on in-vitro cell tests (Bose *et al.*, 2003). Guo *et al.* (2004) instead produced polystyrene molds by SLS, which were then used as molds for PZT ceramic components obtained by gel casting; the selection of the polymer and of the decomposition thermal treatment is essential to avoid deformation of the parts, which was instead observed when using molds produced by FDM of ABS polymer. Ortona *et al.* (2012) applied a technology (“Polyjet”) which dropwise deposits a photo-curable resin to produce a polymeric template possessing a complex, regular three-dimensional cellular structure. In this case, the polymeric template was coated with a SiC slurry and after pyrolysis it was reactively infiltrated with molten Si to generate RBSiC cellular structures with hollow struts. Finally, Franchin and Colombo (2015) used FDM to fabricate polymeric scaffolds which were infiltrated by a geopolymer slurry, resulting in parts with different pore geometries.

Feasibility of AM processing of Monolithic Ceramics

As already mentioned, AM of dense monolithic ceramics is still a major challenge. The problem can be reduced down to a few issues:

- (1) The superior physicochemical properties of advanced ceramics critically depend on their microstructure, which is intrinsically linked to the particle packing of the powder compact and the sintering schedule applied, as well as to their composition (e.g., presence of sintering aids). Obtaining a green compact with the desired microstructure is far from trivial when using AM as an advanced shaping technology. From an economical perspective, this statement should be understood as a well meant advice: the integration of AM technologies into existing industrial ceramic production is a prerequisite for making AM of ceramics reliable, high quality and economically viable.
- (2) Advanced ceramics are generally produced from very fine powders showing a poor flowability. A good flowability is, however, required for the deposition of layers in powder-based AM, such as BJ or SLS. Spreading fine, submicron powders into thin layers is very difficult to impossible. Furthermore, fine ceramic powders are prone to agglomeration and electrostatic charging and, thus, do not pack well. Packing densities of dry ceramic powders in a particle size range from 20 to 100 μm are generally below 50% of the theoretical density (typically between 25% and 45%) (Zocca *et al.*, 2014). The density also depends on the particular layer spreading technology used, i.e., blade, roller etc. The use of ceramic suspensions or pastes, on the other hand, enables deposition of very thin layers, down to 10 μm thickness in case of stereolithography, and the use of finer particulates. After removal of the liquid phase or of the plasticizer, appreciably high densities can be achieved. However, according to the state of the art, the majority of ceramic suspensions or pastes used as feedstock for AM are based on a significant amount of organic binders (40–60 vol%). The removal of organics remaining as a residue in the produced green powder compact is time consuming and restricts the maximum volume or wall thickness of the generated features. Nonetheless, organic plasticizers are favored because their rate of evaporation can be very well adapted to the specific needs of the particular additive manufacturing process. In this context, one of the most successful technologies is stereolithography (SL), using ceramic slurries containing photosensitive resins for the layerwise buildup of ceramic compacts.
- (3) Concerning ready-to-use parts, the first question must be: can the sintering step be directly integrated into an AM process? This would imply that sintering is achieved simultaneously to adding the material. Sintering is a very delicate process step, as it ultimately defines the microstructure of the material, its final physical-chemical properties and has also a strong influence on the parts geometry and dimensional constraints. Therefore, a technology allowing sintering during additive buildup of a ceramic part with physical properties comparable to a conventionally processed part is hard to envision. Based on the selective laser sintering technology, ceramic powders have been sintered layer by layer by the local application of laser energy.

Different to conventional sintering, which works with heating rates of some K at most up to some 10K per minute and dwell times at maximum temperature in the range of hours, the so-called laser sintering requires significantly higher heating rates and provides shorter dwell times. Accordingly, densification of the powder to a non-porous material is hardly achieved. From all the experimental work done in this direction, it can be concluded that short annealing times associated with a local laser irradiation can result in the bonding of particles by the in situ formation of a liquid phase. In this context, two different laser annealing strategies can be applied, on the basis of existing laser systems. The first strategy maximizes the time the material is annealed at a certain position, and laser systems providing continuous laser radiation are used. In the second strategy, lasers providing short pulses, typically of the order of some nano-seconds, are used to apply extremely high radiation intensities. The first approach aims to initiate, similarly to classical sintering, diffusion driven material transport and the formation of a liquid phase for consolidation of powder particles (Kruth *et al.*, 2007). The second approach aims to produce a liquid phase for a short time interval and, by the formation of an ablation plume, an additional force parallel to the surface normal resulting in a compression and fusion of powder particles (Regenfuss *et al.*, 2007).

The formation of a liquid phase is the only way to achieve a rapid densification, which is fast enough to meet the requirements of selective laser sintering technologies. In case an appreciable densification is achieved, cracks are often formed due to the high thermal gradients introduced into the material by the local laser treatment (Juste *et al.*, 2014; Wilkes *et al.*, 2013). To the best of our knowledge, no dense and crack free ceramic parts comprising multiple layers of deposited material could be produced by selective laser sintering or melting up to now. It is noteworthy to observe also that post sintering of laser-sintered and not fully densified ceramic bodies not always leads to a significant additional densification. The local formation of a liquid phase during laser sintering results in extended structural defects in the sintered body, such as larger pores and cracks, which cannot be removed during sintering even though the initial powders used provide a high sintering activity. Furthermore, one must bear in mind, that sintering does not only result in the densification of a powder compact, but also determines the phase composition of the material. In this context, liquid phase formation might provide a route for the rapid densification of a powder compact, but not necessarily results in the desired phase composition and, thus, does not lead to the desired properties of the part generated. Alternatively, sintering could be a final treatment embedded in an AM process. This scenario, however, is basically a direct replication of the powder process chain for the manufacturing of ceramics, in which shaping of a powder compact precedes sintering and, as already mentioned, it must be ensured that the sintering activity of the powders used is not reduced in the AM process prior to the final sintering.

Future Developments

Similarly to what occurred for AM of metals, it can be expected that powder based technologies, in which a powder bed is built up layer by layer, will become the most economically relevant class of additive technologies for ceramics, as their specific merits are: low cost of raw materials, easy scale up to very large parts and parallel processing of multiple parts, high flexibility in design, and direct manufacture of ceramic green bodies with low content of organic additives. However, a very important issue that nowadays remains to be satisfactorily solved is the low powder packing density and stability of the powder bed, when dry powders are used as feedstock, which implies the need of support structures. Instead of dry powders, ceramic slurries can be used for the layer by layer buildup of powder beds with high powder packing densities. Moreover, slurries facilitate the use of powders in a wide range - typically between 100 nm to 100 μm - and classical ceramic processing know-how can be applied for preparing slurries. This concept is already realized in vat polymerization, which at present is the only technology available on the market for AM of advanced ceramics and which will likely dominate marketplaces requiring high precision, small components with complex geometries. Based on these considerations, the following strategies and outlook for the production of high quality ceramic parts via AM can be formulated:

- (1) AM of high quality ceramic parts is inevitably linked to the sintering of powder compacts with appropriate particle size distribution and homogeneous particle packing density;
- (2) Cost-effective AM of high quality dense monolithic ceramic parts must follow the powder processing route of classical ceramic manufacturing;
- (3) The more classical powder processing know-how can be implemented into AM of ceramics, the higher the quality of parts and more cost-effective the manufacturing process will be;
- (4) AM technologies capable of providing powder compacts with appropriate particle size distribution and homogeneous, high particle packing density and with maximum freedom in design will be economically the most successful. Until this goal is reached, the successful implementation of AM technologies for ceramics at an industrial scale will be limited to a few specific material systems and component geometries;
- (5) AM technologies capable of producing complex ceramic parts with very fine (from micro- down to the nano- size scale) filigree but dense lattice structures (struts) will hold an outstanding position within all AM technologies, as ceramic materials are thermodynamically more stable than metals and polymers. In this context, Polymer-Derived-Ceramics (PDCs) can be considered as an enabling technology;
- (6) AM of ready-to-use ceramic parts will remain a challenge, and solutions will likely significantly deviate from the powder processing route of classical ceramic manufacturing.

For the sake of completeness, it should be noted that the preceramic polymer approach to obtain Polymer-Derived-Ceramics (PDCs) offers a viable alternative to the powder processing route, not only in terms of classical fabrication technologies, but also in the context of additive manufacturing. The striking advantage of Polymer-Derived-Ceramics arises from their relatively simple processing starting from polymeric precursors, which enables the components to be fabricated using technologies suited for polymers (Colombo *et al.*, 2017). However, there are several technological challenges associated with the pyrolysis of the polymeric structure into a ceramic. The most critical, in this context, is the release of gaseous species during the pyrolysis of the preceramic polymer, with its associated shrinkage, which prevents the direct production of bulk components. Strategies exist to reduce these issues, such as adding inert or reactive fillers, but the production of fully dense parts remains a challenge. Moreover, most preceramic polymers would lead only to silicon-based ceramics, with boron-based systems being a notable exception (Colombo *et al.*, 2010). Nonetheless, for filigree, porous and small structures, PDCs are an attractive alternative to conventional ceramics, and the presence of carbon nano-sized clusters in their microstructure can afford useful functional properties to the printed parts.

Finally, we should mention that different efforts are currently underway to combine AM technologies with different characteristics in terms of resolution or geometrical capabilities. Hybridization is a term used in the field to indicate the combination/integration (either in parallel or in series) of different technologies to generate components with features typically not obtainable when using a single approach (Bernardino *et al.*, 2020), or to provide additional manufacturing benefits (Gao *et al.*, 2015). Examples include coupling 2PP and DLP, to generate parts with details ranging from the sub-micron to the mm scale, or BJ and DIW, to obtain multi-material components or parts with narrow communicating channels, or DIW and SL, to enable photocuring of the ink and therefore eliminate the stringent requirements on rheology of that extrusion technique, or DIW and SLS, to directly sinter the upon ink exiting from the nozzle.

Green Machining of Ceramics

Fabrice Petit, Belgian Ceramic Research Centre, Mons, Belgium

© 2021 Elsevier Inc. All rights reserved.

Introduction

Although technical ceramics exhibit superior properties (chemical stability, inertness, high wear resistance, strength, refractoriness...) they are very challenging materials for machining by conventional methods such as milling, grinding or turning due to their brittle nature and high hardness. As a consequence machining of ceramics is very expensive and according to [Marinescu et al. \(2007\)](#), it may represent up to 80% of the overall manufacturing expenses. Dense machining is very often a barrier hindering further industrial application.

To overcome these limitations, ceramic parts may also be effectively machined before the final sintering stage either in the “pre-sintered” state or even in the green “non-sintered” compact state. In the pre-sintered stage, conventional machining methods can be applied (milling, drilling, turning) and high material removal rate ($10,000 \text{ mm}^3 \text{ min}^{-1}$) can be obtained (see “Relevant Websites section”). However shrinkage and warping of the ceramic part occurring during the sintering prevents achieving tight tolerances and smooth surface finish. Despite those limitations, this approach is intensively used in the industry as it allows a significant reduction of the machining costs in comparison with parts milled in the dense state.

Machining in the green state is not yet widely studied and documented in the literature. Although it is much more challenging than machining in the pre-sintered stage it also presents several advantages:

- As there is no pre-sintering required, machining in the green state is highly beneficial both from an economical point of view and for environmental issues.
- In the compact state, the blank (i.e., the block to be machined) can be recycled more easily than a pre-sintered body.
- As the green body is basically a collection of grains bound together by an organic phase, its hardness and strength are lower than a pre-sintered ceramic and much less efforts are required to machine it. Potentially, the material removal rate in the green state can be higher than in any other states with less tool wear.
- Finally, non-contact machining operations like laser milling can also be easily used to shape green bodies. This is highly suitable and efficient to create fine features without breakage issues.

Currently, green machining is not yet widely applied in the industry as there is a huge lack of documentation and protocol guidelines. Experimental settings and conditions still remain empirical and/or proprietary information. The main driving force for machining ceramics in the green state is short production runs for which injection molding (CIM) expenses exceeds the cost of green machining. Tooling costs in CIM are so high that it cannot be competitive for producing small batches of parts (most notably when the parts exhibit complicated features like holes, threads...). For those specific cases, green machining is in competition with additive manufacturing (especially SLA – stereolithography). However, in its current state of development, SLA is only compatible to a limited number of ceramics (e.g., silicon carbide is not yet accessible to SLA) and the reliability is not yet at an acceptable level (cracks and other defects tend to be formed during the debinding stage of SLA parts).

Mechanical Machining – The Green Ceramic Cutting Process

In machining, material is removed from a workpiece thanks to the relative motion between this workpiece and a cutting edge. In metals, the cutting process generates a significant heat that causes plastic deformation, chips and curl of the material. In a green ceramic however, the behavior is completely different. The material is removed by a fracturing/crushing process instead than plastic deformation. Small debris taking the form of fine chips of dust are formed but no curl occurs. As there is no need to plastically deform the material, the relative speed between the machining tool and the workpiece can be reduced which also helps increasing the tool lifetime.

In green machining, the crushing effect is not significantly affected by small feeds and depth of cut. Light feed should even be avoided to prevent significant tool wear to occur and inefficient machining conditions. Contrarily to expectation, increasing feed not only increases the material removal rate but also expands the tool life. In terms of settings, the rule is to set the cutting depth to one-third of the tool diameter. [Larson \(1991\)](#) showed that as increasing amount of material is removed with each pass, a lower milling speed should be used to prevent overheating and to allow more time for the removal of the debris.

Formed residues are small agglomeration of grains with size ranging from a few micrometers to several dozens of micrometers (depending from the grain size). To ensure operator safety a dust collection system must be used. Screening of the dust using filters to catch different particle size (down to the nm range) is suitable such that air, free from machining dust, can be rejected.

As any green body contains some organic phases (most notably a binder) one of the main issues in green machining is excessive grains agglomeration in between the cutting edges of the tool. Sometimes grains and debris are not removed fast enough and tend to accumulate on the tool. Cutting becomes less efficient and the level of pressure on the workpiece increases which may

result in cracks or even breakage of the part. To prevent this happening, compressed air blown directly on the tool head helps removing the ceramic particles while maintaining constant fresh cutting edges.

Unlike metals, fixture of green bodies in machining machine can be very tricky. As the material remains very brittle and easily crushable some specific fixtures and chucks have to be used. It has been demonstrated that vacuum works nicely for normal clamping while for lateral clamping a mechanical stop is preferable. Whenever mechanical fixture devices are preferred or necessary, they should be cushioned with a soft material (tape, hard foam...) to prevent breaking during tightening. Too soft materials should be avoided as they will result in deleterious vibrations. Some authors have reported the benefit in using emery cloth wrapped around the ceramic body to prevent slippage.

Mechanical Machining – Green Ceramic Characteristics

Using green machining very complex shapes can be produced more easily than using ceramics in the dense state or pre-sintered ones. However, green bodies of technical ceramics are usually very brittle. Increasing the mechanical strength is therefore a prerequisite for machining. Consequently, the binder system is of primary importance Sheppard (1999). Most common binders are organic compounds like polyethylene glycol (PEG), polyvinyl alcohol (PVA), acrylics or methyl cellulose or even some preceramic polymers. They typically amount to a few weight percent. The typical strength of green bodies does not exceed a few MPa which is still very low. For a green body to be machined a gain of strength of just 1 MPa may be considered as a modest one but it can make all the difference. Usually, green bodies have to be stored in controlled room with a stable temperature and humidity level. Certain aqueous binders are very prone to moisture absorption from air which may affect the dimensions of the green body as well as its mechanical resistance.

Usually, green bodies for machining are obtained through pressing (uniaxial and/or isostatic). There is unavoidably some variation in green density both locally and from part to part. These variations may affect the quality of the machined parts and introduce as well some variability in shrinkage (or warping) during sintering. Isostatic pressing helps reducing significantly the gradient densities within the green body which allows parts to retain their shape during sintering. For most purposes however, the parts obtained after sintering are considered as “near net shape” as the dimensional accuracy is around 20 μm at best (green machining is similar to bisque or pre-sintered machining to that respect). Of course, green machining is not restricted to pressed samples only and it can be used as well in combination with other shaping technologies. Some recent works have considered gel casting instead of pressing for shaping the blank.

Bukvic *et al.* (2012) has shown that there is a direct relation between the machined surface quality and the mechanical strength after sintering (with variations up to 10% of the nominal values). While it may seem as a major drawback, it is always possible to find machining parameters giving smooth surface roughness even in the green state.

Mechanical Machining – Parameters

Different machining procedures exist. Grinding, drilling, turning or milling (to name the principal ones) have all been successfully applied to green bodies. Green machining also took advantage of computer numerically controlled (CNC) machine tools which has further increased the interest of the approach.

For endmilling, drilling or profiling it is usually recommended to use square endmills with a small radius. Carbide tools should be preferred over diamond ones as they can more easily break upon entry especially at high feed rates. If settings are not fine, diamond coatings can also suffer from excessive heating and oxidize. HSS tools durability is usually not satisfactory. For roughing a 2-flute endmills is usually a good option as it reduces the risk of tool breakage from matter packing. For low feed rates and finishing operations a four flutes can be used with more security. The Tables 1 and 2 hereafter show recommended parameters for machining (those are just starting values which have to be fine-tuned depending on the green body characteristics and machine setup).

In terms of tools, not all grades of carbides are satisfactory and very tough grades of carbides should be preferred. K-type grade of cemented carbide seem to offer the best performance both in terms of machining quality and tool durability. They are also more cost effective than diamond tools. Besides being more expensive, diamond cutters can also be much trickier to use (mostly

Table 1 Parameters for drilling green ceramic

<i>Drill diameter (mm)</i>	<i>Peck size (mm)</i>	<i>Feed rate (mm rev⁻¹)</i>
1.0 – 5.0	.25 – 1.25	.025 – .075
5.0 – 6.0	1.25 – 1.5	.025 – .1
6.0 – 8.0	1.5 – 2.0	.025 – .13
8.0 – 10.0	2.0 – 2.5	.025 – .15

because of oxidation issues). However, some authors have reported better machined surfaces and a significant increase in tool life. CBN (cubic boron nitride) cutters exhibit similar performances to diamond ones. Based on the existing knowledge, it seems that specific tools for green machining should be considered: coatings capable of withstanding higher temperatures and providing some lubricating effect should help increasing the reliability and effectiveness of green machining.

Other Approaches for Machining: Laser Milling

To shape a green body conventional mechanical machining is not mandatory in all cases. Other alternatives exist that might be more efficient options to produce certain parts. Since green bodies are brittle, fine features or details still remain challenging to reproduce. As a non-contact technology, laser machining is a clever approach to produce parts having a very high level of details and/or for difficult to machine parts – Samant and Dahotre (2009). The non-contact operation ensures that almost no stress is exerted on the workpiece during machining. Furthermore, thanks to the very small spot sizes of focused laser (typically between 20 μm and 80 μm – e.g., much finer than any existing mechanical endmills) details down to a few dozens of micrometers (or less) can be obtained without part breakage, something that is obviously not possible using mechanical milling.

Laser machining is mostly for cutting or milling. Cutting of green ceramic tapes is commonly used in the electronic industry. Laser used for that purpose can operate in continuous or pulsed mode. As the ceramic is unfired, low average powers are required. Continuous lasers tend to produce a significant heat affected zone – HAZ in the green tape which may affect the cutting quality (ceramic particles may sinter or even melt in the HAZ). For cutting as well as milling, pulsed laser sources are therefore preferred. Matter is then removed not through melting but through ablation which requires high peak power ($> 10 \text{ kW}$) and short pulse duration (from μs down to fs). Nowak *et al.* (2008) explained that in a green body the laser energy is primarily absorbed by the ceramic grains. The surrounding binder (as well as any other organic phase) is then rapidly heated up and vaporizes. Upon vaporization the green body is locally disrupted and the ceramic grains are ejected. A crater is formed. As the laser is continuously moved on the surface of the green body (with speeds up to 3 m s^{-1}), a groove is generated with a depth as high as 0.1 mm in one single pass. Cutting is obtained by repeating the same pattern layer after layer until the laser goes through the whole thickness. Milling is obtained by changing the pattern for each removed layer in order to reproduce a desired geometry.

Laser milling in the green state is not yet widely used. But thanks to a continuous decrease of the prices of laser sources the approach is gaining more and more attention. Usually sources operating in the near IR at a wavelength of 1.06 μm are considered (e.g., Nd:YAG, Nd:YVO₄, fiber lasers). CO₂ lasers are less used for machining because of the poorer resolution they offer (as a consequence of their wavelength, e.g., 10.6 μm) and their trend to enhance the HAZ. However using near-IR lasers is not free from issues. Some ceramics are poorly absorbing in the near-IR region. Alumina or zirconia, for instance have an absorptivity not exceeding 0.2 at 1.06 μm . Although it is still possible to machine those ceramics in the green state, higher powers are required to compensate the poor absorptivity. The process becomes less efficient and the machining quality is often degraded as the HAZ extends further. To improve absorptivity of the green body, a small amount of a specific additive highly absorbing at the laser wavelength can be mixed with the ceramic grains. At 1.06 μm , black carbon or graphite (under different forms: grains, colloids, fibers) are usually selected as their intrinsic absorptivity is very high (> 0.9). Obviously adding of few percent of graphite or black carbon in the green body is not only valuable to enhance the absorptivity (Juste *et al.*, 2014), it also helps reducing the undesirable thermal effects occurring during ablation. In absence of carbon when laser ablation occurs, ceramic grains are ejected from the green body but locally it heats up and local sintering may occur. Whenever carbon is dispersed in the ceramic green body it creates strong diffusion barriers which somehow inhibit sintering. The laser machining becomes almost non-thermal (or cold) even with ns pulsed lasers.

Trends: Hybridization

The combination of conventional mechanical machining with laser machining is a recent trend in manufacturing. The idea is to synergistically combine in one single setup the two approaches and take advantage of both. Usually two discrete sequential processes are employed to achieve the final part specifications. Some recent developments have shown that mechanical milling and laser milling combines very well together. A very promising approach is the combination of mechanical milling for roughing and laser milling to bring fine features to the part and/or to finish it. For metals (but same arguments hold for ceramics as well) hybridization appears relevant in many different ways. Firstly, as one single holistic

Fig. 1 Examples of laser milled Zirconia parts in the green state (the images show the parts after sintering without post-treatment). Courtesy OPTEC – Available at: <https://optec-laser-systems.com/>.

machine is used instead of two, the investment need is dramatically reduced. Furthermore, there is no more any part re-positioning or referencing issues as it is when using different machines. A second advantage is a significant reduction of the machining time and a decrease of breakage risks. Again mechanical milling can rough the parts easily at locations where there is no risk of rupture while the laser can mill the finest features for which there are significant risks of failure. Some ceramics parts have been shown recently which were obtained using this combination of milling approaches (OPTEC – see “Relevant Websites section”). It is obvious that hybridization can capture and combine the strengths of both approaches in a very efficient way (Fig. 1).

Green machining is also promising when it is combined with additive manufacturing (AM). Material extrusion AM (like robocasting or fused deposition modeling of ceramics) is still suffering from the poor resolution of the printed parts. Whenever combined with mechanical machining better geometric dimensioning and tolerances can be achieved as well as improved surface finish and mechanical properties. Such an approach has been pushed forward by Weiss *et al.* (1997). The authors report a hybrid system called shape deposition manufacturing which effectively combines additives and subtractive manufacturing. The principle was demonstrated on polymers but ceramics (hydroxyapatite) as well. Thanks to the hybridization the error in fabricated parts can be reduced well below 1% while it is incredibly higher (> 20%) for parts obtained using deposition only.

Screen Printing

Danjela Kuscer, Jožef Stefan Institute, Ljubljana, Slovenia

© 2021 Elsevier Inc. All rights reserved.

Short History

Screen printing is a method for depositing a patterned layer onto various substrates by pressing a suspension, called the screen-printing paste, through a mesh onto the substrate. The earliest forms of screen printing began in China at the end of the first millennium, and consisted of weaving human hair across a wooden frame as a mesh, with leaves being attached to the hair as a stencil. Later, the process was adapted, by replacing the hair with a piece of silk mounted between two pieces of strong, waterproof paper with some openings cut into them. The paint flowed through the silk, leaving a motive on the substrate (made of ceramic or silk), identical to the openings cut in the paper. This technique, silk-screen printing, arrived in Europe in the late 18th century, but only saw widespread use in the 20th century thanks to the greater availability of silk from Asia. The first screen-printing machine was patented in 1907, and photo-imaged stencils, developed in 1910, led to greatly improved printing quality and control. Initially, silk-screen printing was used to decorate luxury wallpapers and later to print multicolor posters and textiles (Sheng, 1999). In the late 1930s screen printing was, for the first time, applied in the electronics industry as a method for manufacturing capacitor electrodes and later for the processing of hybrid circuit resistor-capacitor networks. Later, the electronics industry rapidly expanded screen printing as a method for packing electronic components in response to the need for the efficient, affordable, large-scale production of thick films. By the 1960s screen printing had become the dominant technology for fabricating printed-circuit boards, which are the basis for almost all consumer electronics (Cote, 1974).

Today, screen printing is integral to the fine arts and the textile industry for decorating fabrics as well as dominating the electronics industry as a mature technology for producing conductive patterns for electronic components, such as touch panels and solar cells, and for various thick-film electronic components, such as sensors and fuel cells.

Screen-Printing Process

Screen printing can be used to reproduce uniform layers or patterns on a substrate. In the conventional screen-printing process the paste is placed on the mesh of the screen mask and the flat substrate is placed under the screen mask. The substrate is held in the holder by a vacuum hold-down system during the printing. A small gap of 0.5–1 mm is kept between the mesh and the substrate. To deposit the pattern onto the substrate, the squeegee, which consists of a polyurethane rubber in a metal support, presses the paste through the open areas of the otherwise filled mesh with a certain speed and force onto the substrate, either manually or automatically. The typical speed ranges from a few to 300 mm s⁻¹ while force ranges from 10 to 200 N. After the deposition, the screen mask is removed, leaving the paste on the substrate. The general principle of the screen-printing process is shown in Fig. 1.

The thickness per screen-printed layer is from a few micrometers to ~ 30 μm. To achieve a thicker deposit, multiple printing steps are performed, including screen printing and curing of the first layer, followed by an overprint of the paste on the cured first layer and drying and curing of the second layer. This process is repeated until the target thickness is reached. At present, 35-micrometer-wide screen-printed lines are used in commercial printed electronics products, while 20–30-micrometer-wide lines are obtained under laboratory conditions for conventional screen-printing technology (Dorey, 2012; Tepner *et al.*, 2019).

The quality of the printed pattern is affected by a combination of many parameters, including the printing parameters, the properties of the screen-printing paste, the properties of the mesh and the screen mask, and the properties of the substrate, all of which need to be optimized and properly adjusted for each individual application.

Screen Mask

The screen mask defines the pattern of the layer and affects the amount of ink deposited onto the substrate. The screen mask consists of a rigid metal frame onto which a mesh, coated with a photosensitive emulsion, is stretched. The common wire-to-frame angles are 22.5, 30 and 45°. The frame has to be flat and structurally stable to provide a stable mesh support that does not affect the dimensional accuracy. The common frame materials are die-cast or extruded aluminum.

The mesh is a weaved cloth of silk, synthetic fibers or metal threads with well-defined windows that reproduce the pattern to be printed. The pattern to be printed is made by coating the mesh with a photosensitive emulsion, usually a polyvinyl acetate or polyvinyl alcohol, sensitized with a dichromate solution. Then the pattern to be printed is masked with a photo-mask and the mesh is exposed to the ultraviolet (UV) light. The photosensitive emulsion that was not exposed to the UV light is washed out with water and becomes the area for printing. (Haskard and Pitt, 1997). A schematic presentation of a cross-section of a mesh is illustrated in Fig. 2.

The material of the mesh is selected based on the properties of the paste and the target application. The material must be chemically inert with mesh openings that are as equal as possible, suitable mechanical properties and sufficient life time. The most

Fig. 1 Schematic presentation of the screen-printing process.

Fig. 2 Scheme of the cross-section of a mesh. D is the diameter of the mesh element.

frequently used materials for the mesh are polyamide (nylon), polyester and stainless steel. The polyamide and polyester are available as monofilaments with diameters from $\sim 30 \mu\text{m}$ to a few hundred μm . Both materials are resilient, strong and elastic, with a high extensibility of 4%–6%. The polyamide and polyester meshes easily deform, which results in a distorted shape and a relatively thin printed pattern. The higher elasticity of polyamide compared to polyester makes it possible to print on uneven substrates, but the tendency to absorb water limits the printing accuracy and consequently polyamide meshes are used less frequently than polyester. A polyester-based mesh is sufficiently flexible for printing on substrates with normal irregularities. It is characterized by a higher tension, better dimensional accuracy and longer life time compared to polyamide. Polyester-based meshes are used for applications where the high resolution of the patterns is not of paramount importance, but production costs need to be limited.

A mesh based on stainless steel is characterized by thin and uniform wires with a diameter from $15 \mu\text{m}$, a consistent mesh thickness with evenly tensioned waves having a very low extension of 0.5% and a high tensile strength, which makes it possible to print patterns with high definition and good printing accuracy. The flattened standard stainless mesh, i.e., the calendared stainless-steel mesh, is thinner, smoother and more uniform than standard mesh and allows the printing of layers with excellent definition. The poor flexibility of the stainless steel means that it is possible to print solely onto flat surfaces, and thus the stainless-steel meshes are used for realizing very-high-resolution patterns on flat and relatively small surfaces (White, 1994). Stainless steel meshes are largely used in electronics.

The factors influencing the characteristics of the printed layers include many parameters, such as the number of mesh elements, i.e., wires or fibers, per inch (mesh count, M), the type and diameter of the mesh element, the tension, the wire-to-frame orientation, the type and thickness of the photosensitive material, the exposure time, the dimensional accuracy of the photomask etc.

For a given mesh count $M [\text{in}^{-1}]$ the smaller diameter of the mesh element is reflected in larger mesh openings, which results in a larger volume of the printed paste. Thus, the mesh count is one of the factors controlling the thickness of the deposit. The percentage of open area (OA) is defined as $[1 - (M \times D)]^2$, where M is the mesh count and $D [\text{in}]$ is the diameter of the mesh element. Knowing the OA, the mesh thickness (MT), and the thickness of the emulsion (ET) we can estimate the wet thickness of the printed pattern $WT = (MT \times OA) + ET$. For most applications the ET is $\sim 13 \mu\text{m}$.

Another important parameter is the size of the mesh openings, which must be at least 3–5 times larger than the size of the particles or agglomerates in the screen-printing paste.

Properties of the Screen-Printing Paste

A stable and homogeneous paste is of great importance to the screen printing of uniform patterns in a reproducible manner. Furthermore, the paste needs to be formulated in such a way that it possesses good printability and provides uniformity and a good aspect ratio of the printed pattern.

Fig. 3 (a) Viscosity of the ceramic paste (60 wt% of $K_{0.5}Na_{0.5}NbO_3$ and 40 wt% organic phase) as a function of shear rate. (b) Viscosity of the ceramic paste as a function of time and shear rate.

The paste consists of an active material distributed in a certain solvent. In the case that the active material is a powder, the particles sediment over time, if gravity overcomes the Brownian motion. In addition, the particles spontaneously agglomerate as a result of the van der Waals attractive forces. The sedimentation and agglomeration reduce the quality of the printing pattern and need to be avoided. To prevent agglomeration and sedimentation of the particles it is necessary to introduce repulsive forces between the particles, either by charging the particles or by preventing their close approach with steric hindrance.

In electrostatic stabilization, the interactions between the particles and the solvent yield a charge on the surface of the particles as a result of the ionization of the surface groups, ion adsorption, dissolution of the ions or the isomorph substitution of ions. Electrical repulsion is an important type of stabilization for particles dispersed in water-based systems or in liquids with a moderate polarity, like alcohols. In these systems the stability of the particles is controlled by the particle size, ion type, its concentration and the value of the zeta-potential. The zeta-potential of a particle with an absolute value over 25 mV results in a stable suspension.

In steric stabilization the particles are covered by a layer of uncharged polymers, either through the adsorption or through chemical grafting. The polymer layer physically prevents the close approach of the particles. To keep the particles well dispersed in a solvent the polymer must be strongly adsorbed on the particles, must completely cover the surface of the particle, while the concentration of the non-adsorbed polymer must be low. Steric stabilization is appropriate for stabilizing the particles in low-polarity solvents.

Electrosteric stabilization is a combination of the electrostatic and steric stabilization mechanisms. It utilizes a polyelectrolyte with a long-chain polymer and a functional group. The functional group can dissociate in the solvent, thereby creating charged moieties that contribute to the electrostatic effect, while the polymer chains contribute to the steric hindrance. Examples of polyelectrolytes are polyacrylic acid with a carboxylic group that dissociates at high pHs and polyethylene amine with an amino group that dissociates at low pHs.

The printability of the paste is directly related to its rheological properties, in particular to the shear-rate-dependent viscosity and thixotropy. During the printing process the paste is mechanically forced through the mesh. The resistance of the paste to flow is determined by means of viscosity, defined as the ratio of the shear stress (τ) to the shear rate (dy/dt). A high viscosity means a high resistance to flow and vice versa. The viscosity of the paste can be independent of the shear rate (Newtonian behavior), shear-thinning where the viscosity decreases with the shear rate or shear-thickening where the viscosity increases with the shear rate. The composition of the screen-printed paste should be designed to be shear-thinning (**Fig. 3(a)**). The paste is put on the mesh before printing and while it rests, the viscosity of the paste should be high. During printing under the pressure of the squeegee, the viscosity of the paste should decrease to be able to flow through the mesh. However, once the pattern is formed on the substrate, the viscosity of the paste must increase within a short time period to maintain the high-definition shape of the pattern (**Fig. 3(b)**). The printing step takes into the consideration the change in viscosity with the shear rate, while the last step includes the change in viscosity with time, evaluated as the thixotropy. Thixotropy covers the reduction of the structural strength of the paste by a shear process and the structural regeneration of the paste in a subsequent period of rest (*Mezger, 2006*). The shear rate during printing is typically between 100 and 1000 s^{-1} , and pastes with a viscosity up to 150 Pas at 100 s^{-1} are generally suitable for screen printing (*Reed, 1995*).

Chemical Composition of the Screen-Printing Paste

The composition of the paste for screen printing is complex and consists of an active material, solvent and various additives, such as a dispersant and a binder. The solvent serves as a dispersion medium for the active material and a medium to dissolve all the

Fig. 4 Rotary screen printing.

other components. Traditionally, organic-solvent-based pastes have been used for screen printing. Terpineol (2-(4-methylcyclohex-3-en-1-yl)propan-2-ol) and texanol (2,2,4-trimethyl-1,3-pentanediol monoisobutyrate) with boiling points of 219 and 254°C, respectively, are commonly used solvents. As the major phase the solvent dictates the properties of the paste, in particular the drying and wetting behaviors. If the drying rate is too fast, defects can form in the printed pattern, while a slow drying rate results in a wet pattern for a long time and consequently difficult handling of the sample, possible phase separation and losing the accurate dimensions of the printed pattern. Wetting is an important parameter that controls the dispersion of the active materials in the solvent and also the behavior of the paste on the substrate. The contact angle θ measures the wetting tendency of a liquid on a solid and is related to the surface energies of solid-vapor γ_{SV} , solid-liquid γ_{SL} and liquid-vapor γ_{LV} : $\cos\theta = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}}$.

A small contact angle indicates that the liquid spreads on the solid surface, which results in poor definition of the pattern, while large contact angles with well-defined drops of liquid indicate a poor wettability of the solid. The wettability of the solid can be improved by surfactants, whose short-chain molecules consist of hydrophobic (oil-soluble) and hydrophilic (water-soluble) parts. Such molecules have a tendency to adsorb very strongly at the solid-liquid or vapor-liquid interfaces, causing the removal of the hydrophobic part from the aqueous media, while the hydrophilic part remains in the water. They form new surfaces with a lower energy, which improves the wettability (Hunter, 2009). The approach to enhance the wettability of the paste on the substrate is also to clean the substrate with solvent or to treat the substrate with plasma.

Dispersants are added to screen-printed pastes to increase the repulsive forces between the particles and thus to improve the long-term stability of the paste. Dispersants are long-chain molecules that adsorb onto the particles and stabilize the particles using a steric or electrosteric mechanism. The dispersants, such as polyethylene glycol, pentastearic acid oligomer, and alcohol polyoxyethylene phosphoric acid ester, with a content of a few wt%, are frequently used in screen-printing pastes. The dispersant also decreases the viscosity of the paste, which makes it possible to process the paste with a large number of particles, i.e., a higher solids load. The maximum acceptable solids load in the paste is determined by the particle size and the particle size distribution, as well as by the amount of solvent and additives. Typical solids loading ranges from 40 to 60 wt%. The patterns fabricated with a low solids loading have a tendency to crack and delaminate due to the large shrinkage of the pattern during the drying and debinding processes, while high-solids-loading pastes result in a thicker layer with a high surface roughness.

Binders are additives used in screen-printing pastes to improve the particle network in the as-printed pattern and thus provide the strength for handling. The binders consist of polymer molecules that adsorb onto the particles and bridge the particles. They prevent the formation of defects and enable adhesion of the paste to the substrate after drying. The binders can be roughly classified based on the composition of the inorganic and organic binders or based on the structure of the particle and molecular types. In screen-printing pastes the organic, molecular-type binders are the most frequently used, e.g., ethylene cellulose, polyvinyl butyral, polyvinyl acetate, and polymethyl methacrylate. The amount of binder in the paste, commonly added in the amount of 1 wt%, has an impact on the rheological properties of the paste. Too high an amount of the binder can affect the printability and reduces the quality of the printed pattern.

Water-based systems for screen printing have been investigated less intensively, regardless of increasing environmental and health concerns. For example, the screen printing of Ag nanoparticles was realized by dispersing 77 wt% of the particles in a mixture of water and polyethylene using polyacrylic acid as a dispersant (Hyun *et al.*, 2015).

In addition to organic-solvent- and water-based systems, polymerizable pastes can be used for screen printing. The composition of such a paste is complex and contains monomers, polymers, initiator, active material such as particles and additives to enhance certain properties, for example, shelf life, adhesion, and wettability. Most formulations contain a complex mixture of numerous monomers and oligomers to obtain suitable rheological properties of the paste for the printing process. The monomers and oligomers are predominantly acrylates that undergo radical polymerization initiated by reactive species from the initiator. The common initiators generate radicals under thermal or ultraviolet (UV) curing. Thermal curing needs temperatures up to 200°C and curing times up to a few tens of minutes, while UV curing requires exposure of the paste to UV light, commonly in the range of 200–400 nm for less than 1 min (Licari and Swanson, 2011). The advantages of UV curing are the almost instant drying of the

Fig. 5 Schematic presentation of screen-off-set printing. (a) Screen-printing of the paste onto a blanket. Transformation of the paste to the flat (b) and curved surface (c).

paste, solvent-free pastes, adhesion of the paste to various substrates, low costs and a fast production process (Edison, 2010; Hutchinson, 2010).

The typical method for the preparation of the paste includes the weighting of the constituents and their homogenization in a three-roll mill. This mill is composed of three rollers rotating in opposite directions at different speeds relative to each other that squeeze the material through the adjustable gaps and thus mixes, disperses or homogenizes the paste.

Alternative to Traditional Screen Printing

Rotary screen printing uses the same principle as conventional screen printing, but in this case cylindrical-shaped masks are utilized as illustrated in Fig. 4. A paste is located inside the cylinder together with a squeegee at a fixed position. As the screen rotates with the same speed as the substrate the paste is continuously pressed through the mesh by the squeegee forming a pattern onto the substrate.

Rotary screen printing is widely used in the textile industry and recently in electronics for the metallization owing to the fact that it is a continuous process that allows for a high printing speed up to 1700 mm s^{-1} , and thus, reduced costs. However the cylindrical masks are quite costly and difficult to clean (Lorenz *et al.*, 2017).

Screen-offset (SOS) printing and screen-offset curved-surface (SOS-CS) printing are based on screen printing the paste onto a cylindrical silicon blanket (Fig. 5(a)) and the subsequent transformation of the paste onto the substrate. In SOS printing the substrate is flat, while in SOS-CS printing the substrate is curved (Fig. 5(b) and (c)).

In the first step the paste is put on the flat mask, which moves as a consequence of the rotation of the blanket. The squeegee is at a fixed position and forces the paste through the mesh openings onto the blanket. The pattern printed onto the silicon blanket retains its original shape due to the ability of the blanket to absorb the solvent from the paste. In the next step the pattern is transformed from the blanket to the flat or curved substrate.

This technique enables the printing of patterns with thicknesses of $5\text{--}7 \text{ }\mu\text{m}$ and a minimum line width of $\sim 15 \text{ }\mu\text{m}$. The pattern is characterized by a rectangular and well-defined shape. Multiple printings (2 passes) results in thicker patterns of $12\text{--}15 \text{ }\mu\text{m}$ and a similar rectangular shape. This technique is highly applicable in the electronics industry in response to the growing demands for printing low-width, high-thickness patterns on curved surfaces (Nomura *et al.*, 2018).

This chapter is an update of Leriche, A., Cambier, F., Hampshire, S., 2017. Sintering of ceramics. Reference Module Materials Science and Materials Engineering. doi:10.1016/B978-0-12-803581-8.10288-7.

Introduction

Ceramics are inorganic, non-metallic materials, produced from minerals or synthetic powders which are formed into a shape and consolidated by a high temperature process to densify and strengthen the material and reduce the porosity. Traditional ceramics including pottery and industrial products such as whitewares, heavy clay-ware, and building materials are formed mainly from natural aluminosilicates and the presence of other minerals including micas and feldspars and some impurities leads to molten viscous phases at the firing temperature. In contrast, advanced ceramics are pure oxides or non-oxides (nitrides, carbides, borides, etc.) or composites of these and include materials that have been developed with designed microstructures for (1) structural applications, making use of their mechanical, tribological or high temperature properties for cutting and drilling tools, bearings, seals, dies, engine components, and coatings on other materials to improve corrosion resistance or thermal stability, and (2) functional applications, such as electronic, dielectric and magnetic components, biomedical implants or devices, filters, membranes, and catalyst supports.

Most ceramic materials are processed from powders which are shaped and then densified during a heat treatment, where the temperature is sufficiently high, in the range $0.5\text{--}0.8 T_m$ (where T_m is the melting point) to allow diffusion of material. To favor the densification, uniaxial or isostatic external pressure can be applied during thermal treatment (Hot Pressing or Hot Isostatic Pressing as opposed to Pressureless Sintering). In addition, an electric current can be used simultaneously with uniaxial pressure (Spark Plasma Sintering) or without pressure (flash sintering) or microwave heating can be applied in order to improve the process. A more recent technique called “Cold Sintering” which uses a transient transport phase, most often liquid, and an applied uniaxial force, to assist in powder compact densification is also briefly described.

Thermal Treatment of Ceramics – Sintering

General Outline

Owing to the generally high melting points of the raw materials involved, the fabrication of ceramic materials commonly includes a heat treatment in which a powder, already formed into a required shape, is converted into a dense solid. The matter transport to reduce the porosity occurs by diffusion of atoms in the vapor phase, in the liquid phase or in the solid state, or by viscous flow of a glassy phase. Most mechanisms are activated thermally because the action of temperature is necessary to overcome the potential barrier between the initial state of higher energy (porous powder compact) and the final state of lower energy (consolidated dense material).

The term sintering is used to refer to all the phenomena occurring during heating, leading to the densification of a powder compact. There are three main types of process for this consolidation to take place and these are dependent on the composition being fired and, in particular, on the extent to which a liquid phase is formed during heat treatment:

- (1) “Solid State Sintering” in the absence of any liquid phase,
- (2) “Liquid Phase Sintering” in the presence of a small volume percent of liquid phase,
- (3) “Viscous Flow Sintering” when the liquid phase volume is high and similar to the porosity of the powder compact.

In all cases, the driving force for densification lies in the reduction of the surface energy resulting from the reduction in the interfacial area between gas and liquid/solid phases. Fig. 1 shows a schematic view of the three types of sintering mechanisms.

In this chapter only the Solid State Sintering and Liquid Phase Sintering mechanisms will be presented as the Viscous Sintering concerning mostly the clay based ceramics or glasses is largely described by Scherer (2019).

The green density of the shaped powder compact is usually around 55–60 vol%. This means that full densification of the ceramic will be accompanied by a large amount of shrinkage (decrease of dimensions) of approximately 35 to 40 vol% and 18–20 linear %. There is also a change in shape of the powder particles with time usually resulting in an increase in average grain size. As shown in Fig. 2, the densification rate of a powder compact heated at fixed temperature decreases with time.

The shrinkage of the ceramic compact can be followed at different stages of the process using dilatometry as shown in Fig. 3. At the beginning of heating, the sample expands due to increase in the amplitude of thermal vibration of atomic bonds. At higher temperatures, densification commences with reduction of porosity. When the thermal treatment is maintained after complete

Fig. 1 Sintering mechanisms.

Fig. 2 Schematic curve of densification of a powder compact with time.

Fig. 3 Classical dilatometric curve.

densification, in some instances, expansion (or dedensification) can occur provoking the appearance of residual porosity and is often associated with initial grain growth.

As shown in **Figs. 2** and **4**, sintering can be presented in three stages:

- (1) Initial stage, during which necks are growing at contact points between particles,
- (2) Intermediate stage (65%–90% density), during which pores become cylindrically shaped with interconnections, so-called “open porosity”,
- (3) Final stage (90%–100% density), during which pores become more spherical and isolated: “closed porosity”.

The total interfacial energy of a powder compact is expressed as γA , where γ is the specific surface or interfacial energy and A is the total surface or interfacial area within a powder compact. The reduction in this total energy can be expressed by (Kang, 2005):

$$\Delta(\gamma A) = \Delta\gamma A + \gamma \Delta A \quad (1)$$

The change in interfacial energy, $\Delta\gamma$, is due to densification and the change in interfacial area, ΔA , occurs because of grain coarsening. $\Delta\gamma$ is related to replacement of solid/vapor interfaces (particle surfaces) by solid/solid interfaces (grain boundaries).

Then, the reduction of total interfacial energy occurs through densification and grain growth (coarsening) as shown schematically in **Fig. 5** (Kang, 2005).

Fig. 4 Grain shape modification during sintering.

It has been shown that the grain growth becomes predominant during the final stage as illustrated in **Figs. 6** and **7** for sintered titania (Rahaman, 1995) and alumina (Madhav Reddy *et al.*, 2010) powders.

Solid State Sintering

Description of matter transport mechanism

In solid state sintering, the densification relies wholly on diffusion of atoms (1) at the surface, (2) through the volume, or (3) at grain boundaries with no formation of liquid.

In the absence of liquid phase, the reactions within and between solids require the mobility of atoms and ions. The mechanism of diffusion in solids is the movement of atoms or ions either into vacant lattice sites (vacancies) or between positions that are not normally occupied (interstitial sites).

The driving force for sintering can be described from a macroscopical view as the decrease of free energy by replacement of solid–gas interfaces by solid–solid interfaces and from a microscopical view as the free energy (pressure P) difference across a

Fig. 8 Shrinkage and shape change of two joined grains.

curved grain boundary. The difference in free energy between the neck area and the surface of the particle provides a driving force which causes the transfer of material by the fastest means available.

The diffusion of atoms occurs in the reverse direction to vacancies which move from areas of higher concentration to ones of lower concentration that is from concave surfaces to convex surfaces. As presented in **Fig. 8**, the necks between spherical particles are the sink of matter with a diffusion rate as high as the grain curvature ($1/r$) is high (the case of small particles). The driving force P (a few MPa) decreases as sintering progresses, which explains the decrease of densification rate:

$$P = \frac{\alpha\gamma}{r} \quad (2)$$

The matter flux “ J ” induced by the pressure difference “ P ” can be expressed by the following **Eq. (3)** where D is diffusion coefficient, x the transport distance and T the temperature:

$$J = -\frac{D}{kT} \frac{dP}{dx} \quad (3)$$

The value of the diffusion coefficient depends on the transport mechanisms that may operate during solid state sintering of a polycrystalline ceramic and these are shown schematically in Fig. 9 and are classified in Table 1.

The first three mechanisms with the surface as the source of matter lead to neck growth but no shrinkage and include:

- (1) *Vapor transport* D_g : which allows material to be transported from one source surface to another sink surface by evaporation of atoms and condensation at another site, through the pore network. This can also take place because of vapor pressure difference Δp .
- (2) *Lattice diffusion* D_l : which allows material to be transported from a particle surface to the neck area by diffusion through the bulk lattice with no increase in densification of the material.
- (3) *Surface diffusion* D_s : which involves the diffusion of atoms along surfaces where the source is a particle surface and the sink is a neck. It only occurs to a depth of approximately one to two atomic distances (0.3–0.5 nm) (Rahaman, 2003). This type of diffusion is initiated at lower temperatures due to its lower activation energy and is usually the dominant mass-transport mechanism during the early stages of neck growth, as the compact is heated up to the sintering temperature. It becomes less dominant as neck formation between particles increases.

The final three mechanisms with grain boundaries or the bulk material as the source of matter do lead to shrinkage and include:

- (4) *Plastic flow* η : which is only active where there is a very high initial dislocation density and therefore is not usually operative in ceramics.
- (5) *Bulk lattice diffusion* D_l : also called volume diffusion which allows atoms from the grain boundary to be transported from the grain boundary through the lattice to a neck or pore surface and so the boundary acts as a site for vacancy annihilation.
- (6) *Grain boundary diffusion* D_b : which allows atoms from the grain boundary to be transported along the grain boundary to a neck region or pore surface, driven by the high level of disorientation of the atoms along the grain boundary. Even though grain boundaries are quite narrow they are very active transport paths.

Overall, there is a competition between densification and grain growth and to obtain dense and fine grained ceramics, it is necessary to favor the material transport mechanisms leading to shrinkage and to limit the surface diffusion mechanisms.

The activation energies for surface, grain boundary, and lattice diffusivity increase in that order (Barsoum, 2002) as shown in Fig. 10 and so the type of matter transport mechanism in operation is highly dependent on the sintering temperature. Thus, surface diffusion is favored at lower temperature whereas bulk lattice diffusion is favored at higher temperatures:

Fig. 9 Transport mechanisms operating during solid state sintering.

Table 1 Different atom diffusion paths in solid state sintering

$$J = -\frac{D}{kT} \frac{dP}{dx} \quad D_i = D_{0i} e^{-\frac{Q_i}{RT}} \quad (4)$$

The diffusion coefficient is also affected by impurity solutes. In general the presence of solutes which enhance either boundary or volume diffusion coefficients increases the rate of solid-state sintering. For oxides in which the slowest diffusing species is oxygen, the addition of cations with lower valence state or the use of reducing atmosphere will enhance sintering (e.g., Li_2O in NiO). If the slowest diffusing species is a cation (as for ZrO_2 , Y_2O_3 , UO_2 , etc.), the addition of a higher charged valence state cation will increase the number of host cation vacancies and will thus enhance sintering (e.g., TiO_2 into Y_2O_3).

Fig. 11 presents a typical schematic figure of the microstructure of an oxide and a SEM micrograph of a pure oxide (zirconia) after thermal etching. Typically the microstructure of a sintered oxide ceramic consists of equiaxed grains with residual porosity and little or no glassy phase at grain boundaries.

Grain growth mechanisms (GG)

The driving force for grain growth is the difference in energy between a fine-grained material and one with a larger grain size resulting from the decrease in grain-boundary area and total boundary energy. As the average grain size increases, it is obvious that some grains must shrink and disappear. Due to the free energy difference across a curved grain boundary, the atoms move from a concave to a convex interface and the grain boundary moves toward its center of curvature until the grain disappears (**Figs. 12** and **13**).

The grain growth velocity, v_B , can be estimated from atom flow, J , through a grain boundary:

$$v_B = J\Omega \quad (5)$$

$$J = \frac{D_b}{kT} \frac{\Delta P}{dx} = \frac{-D_b}{kT} \frac{\alpha\gamma}{r} \frac{1}{\delta_b} \quad (6)$$

Property Control by Processing. Chapman & Hall.

$$\frac{d(GG)}{dt} \sim d^{-2} \quad (7)$$

where Ω is atomic volume and δ_b the grain boundary thickness.

Simultaneously, with normal grain growth, exaggerated grain growth (EGG) can occur as illustrated in Figs. 14 and 15. This phenomenon can be avoided by addition of dopants which segregate at grain boundaries (e.g., ~300 ppm MgO in alumina).

Simultaneously with grain growth, pore shape distortion can occur from a spherical shape by the moving boundary and pore agglomeration. The stability of a pore depends on both the dihedral angle and the number of surrounding grains which gives N_c , the critical number of grains surrounding a pore as shown in Figs. 16 and 17. When the number of surrounding grains is higher than N_c for a given dihedral angle, the pore size increases and it decreases when the number of surrounding grains is lower as illustrated Fig. 18 (Kingery *et al.*, 1960).

The pore stability conditions change with pore size as shown in Fig. 19 (Ewsuk and Messing, 1989). The larger is the pore, the greater will be the dihedral angle to eliminate the pore. When grain growth occurs, many pores become isolated from the grain boundaries and the diffusion distance between pores and a grain boundary becomes large, and the rate of sintering decreases. The most satisfactory way of obtaining densification is to prevent or to slow boundary migration by various methods like segregation of dopant at grain boundary or addition of inclusions provoking a pinning of grain boundary.

Liquid Phase Sintering

Description of matter transport mechanisms

Contrary to sintering by viscous flow, the liquid volume formed by the partial melting of one or more components has to be limited to a small volume percent in order to keep the compact shape and to limit the amount of glassy/amorphous phase in the

Fig. 17 Conditions for pore stability versus surrounding grain number.

(Eds.), Proceedings of the 2nd International Conference on HIP: Theory and Applications, pp. 23–33. ASM International.

final product. It is represented in **Fig. 20** as a low thickness liquid layer around each particle. The matter transport occurs by atom diffusion through the superficial liquid phase (D_{liq}):

$$J = - \frac{D_{liq}}{kT} \frac{dP}{dx} \quad (8)$$

Therefore, the parameters which control densification include grain size and shape, pore size and shape, liquid volume and viscosity, solubility of the solid, wetting of the solid by the liquid, phase distribution and phase-boundary energies.

Fig. 20 Superficial liquid phase on two spherical particles.

Fig. 21 (a) liquid drop on solid substrate showing contact angle, θ ; (b) liquid penetration along grain boundary depends on dihedral angle, Φ . Reproduced from Smith, C.S., 1948. Grains, phases and interfaces – An interpretation of microstructure. Transactions of the American Institute of Mining Engineers 175, 15–51.

Consider a drop of liquid resting on the surface of a solid phase (Smith, 1948), as in Fig. 21(a), the system will reach equilibrium such that:

$$\gamma_{SV} - \gamma_{SL} = \gamma_{LV} \cos \theta \quad (9)$$

where γ is the surface energy of the respective interfaces (SV – solid/vapor; SL – solid/liquid; LV – liquid/vapor).

If $\theta < 90^\circ$, then the liquid wets the solid.

If $\theta = 0^\circ$, the liquid will spread along the solid surface but complete wetting cannot occur if $\gamma_{LV} > \gamma_{SV}$.

If the liquid is surrounded by the solid as in a pore, the conditions are slightly different because spreading generates only new liquid–solid interface but no new liquid–vapor interface. A wetting liquid will always tend to rise up a capillary or be drawn into a pore, even if it would not spread on a free surface. Where the liquid phase is in contact with a solid grain boundary as in Fig. 21(b), penetration of the liquid between the grains will be dependent on the surface energies involved:

$$\text{At equilibrium: } \gamma_{GB} = 2\gamma_{SL} \cos(\phi/2) \quad (10)$$

where ϕ is the dihedral angle. In the case of complete wetting, the liquid phase can penetrate along the grain boundaries and separate the grains.

To be efficient, the liquid phase should wet the grains and penetrate along the grain boundary. For this to occur, the dihedral angle must be less than 60° as shown in Fig. 22.

It was shown that increasing the dihedral angle and the degree of solid–solid contact between grains tends to increase the resistance to shrinkage and densification (Jackson *et al.*, 1963). This occurs mainly during the initial rapid formation of the liquid phase when any grain-to-grain contact inhibits the ability of the particles to rearrange within the liquid phase.

The driving force for densification is derived from this capillary pressure of the liquid phase located between the fine solid particles. Each interparticle space becomes a capillary in which capillary pressure is developed. For submicron particle sizes, capillaries with diameters in the range of $0.1\text{--}1\text{ }\mu\text{m}$ develop pressures in the range of $1.25\text{--}12.5\text{ MPa}$.

The presence of liquid and the capillary pressure result in densification via three distinct stages:

- (1) Particle rearrangement stage.
- (2) Solution-diffusion-precipitation stage.
- (3) Coalescence stage.

During the first stage, the liquid which is first formed is drawn by capillary forces to the points of contact between grains at a rate which is determined by the surface tension and viscosity of the liquid. Particle rearrangement thus occurs by viscous flow. The proportion of complete densification that can be achieved through a rearrangement process with spherical particles depends on the volume fraction of liquid present (Fig. 23).

The shrinkage may also depend on particle shape and size distribution, the solubility of the solid in the liquid and interfacial energies.

The second stage involves atom transport in the liquid by solution, diffusion and reprecipitation and proceeds in three steps: (1) atom migration to the grain surface followed by interfacial reaction leading to dissolution of solid in the liquid phase; (2) matter transport by diffusion through the liquid to points away from the contact areas; and finally (3) the re-precipitation of solid material either at grain boundaries or on existing seed crystals (e.g., in silicon nitride, where initially α -silicon nitride is dissolved and β -silicon nitride precipitates on existing β seeds).

For very small crystals, the interfacial tensions between the crystals and their saturated solution are greater than that for large crystals. According to the Gibbs–Thompson equation, the solubility of small grains is larger than large grains:

$$\log \frac{S_r}{S} = \frac{2M\gamma}{N_0 k T \rho r} \quad (11)$$

where S_r and S are solubilities of particles with radius r or infinite radius, M is molar mass, γ is surface energy, k is Boltzmann's constant, T is absolute temperature, ρ is particle density, and r is grain curvature radius.

The third stage of sintering involves a reduction in the densification rate which may be caused by a number of different processes including (1) grain growth which prevents further transport of liquid phase, (2) trapping of gases in closed pores with the resulting pressure acting against the capillary pressure normally causing shrinkage, etc.

Successful systems require sufficient liquid volume, a good wettability of the powder particles by the liquid and partial solubility of the solid in the liquid.

Fig. 24 shows typical examples of microstructures: (1) mullite-zirconia composites synthesized by reaction sintering from zirconium silicate and alumina and (2) silicon nitride with $\text{MgO}/\text{Y}_2\text{O}_3$ as sintering additives. The chemically etched

microstructures show needle-like elongated grains of mullite or silicon nitride. The glassy phase formed by cooling from the liquid phase is located at grain boundaries.

Grain growth mechanisms

For Liquid Phase Sintering, the grain growth can be controlled either by the dissolution step or by the diffusion step.

In the case of the rate control by diffusion, the grain growth follows the relationship:

$$d^3 - d_0^3 = k_1 t \quad (12)$$

where d_0 is initial grain size and k_1 is a constant depending on D_L , Ω , C , γ_{SL} , k , T .

A similar dependence exists for a model described for the creep of materials containing an intergranular liquid phase (Raj and Chyung 1980):

$$\frac{d\varepsilon}{dt} = \frac{3.7 \sigma \Omega C \alpha}{(1-x) \eta d^3} \quad (13)$$

where ε is the strain, σ is the applied stress, η is viscosity of the liquid, C is molar content of solute in the liquid phase and x is the amount of liquid. This relationship has the advantage of showing the influence of liquid viscosity on diffusion rate.

If the grain growth is controlled by the interfacial reaction (as occurs in the case of a low viscosity liquid), the phenomenon can be described by the relationships in Eq. (14) giving square of grain size, d^2 , dependence and the liquid phase viscosity does not affect the grain growth rate:

$$d^2 - d_0^2 = k_2 t \quad k_2 = \frac{256 C \Omega \gamma_{SL} k_R}{81 k T} \quad (14)$$

where k_2 is a constant depending on Ω , C , γ_{SL} , k_R (the atom transfer rate between crystal and liquid), k , T .

The comparison with the creep rate model for dissolution reaction gives a different dependence with grain size:

$$\frac{d\varepsilon}{dt} = \frac{\sigma \Omega K'}{2(1-x)k T d} \quad (15)$$

where x is the surface volume fraction occupied by the liquid at the grain boundary.

Densification Kinetics

The rate of growth of the neck during the initial stage was analyzed for various mechanisms of transport of material into the neck from the particle surface (Kuczynski, 1949) and the effects of particle size were included after by Herring (1951). For all mechanisms, a general relationship follows:

$$(x/r)^n = K_1 t / r^m \quad (16)$$

where r is particle radius, x is the radius of the interparticle contact area, t is time and n , m and K_1 are constants. Plots of $\log(x/r)$ versus $\log t$ or $\log r$ should result in linear plots with slopes of n or m .

During the second intermediate stage, depending on the mechanism of material transport, shrinkage may occur according to:

$$\Delta L / L_0 = K_2 t^y \quad (17)$$

where ΔL is change in length, L_0 is original length, t is time, and y and K_2 are constants. A plot of $\Delta L / L_0$ versus $\log t$ should be linear with slope y .

The mechanism of material transport is then deduced from the slope as follows (Table 2).

Particle size, packing, degree of agglomeration, presence of impurities, sintering atmosphere, etc., can affect the mechanism of sintering, the extent of pore/grain boundary interactions (Brook, 1969) and whether densification or coarsening occurs.

Fig. 25 shows schematic curves of relative density versus time and the effects of temperature, pressure, and particle size (Kang, 2005).

Increase in temperature favors atomic diffusion through the Arrhenius relationship, external pressure will increase the sintering driving force (γ/r) and decrease in grain size decreases the diffusion distance. For an identical particle size, a temperature increase favors successively D_s , D_b , and D_l . So, low temperature sintering favoring D_s (neck growth without shrinkage) will be chosen to process porous materials, whereas achievement of high densities will require high temperature sintering to favor D_l (shrinkage).

Pressure and/or Plasma Assisted Sintering

Densification of ceramics can be achieved more effectively using pressure-assisted forming techniques which combine external pressure with temperature in order to enhance the final density. These include hot pressing, hot isostatic pressing, sinter forging, hot extrusion and gas pressure sintering. More recently, electrical field assisted sintering techniques have been developed.

Table 2 Deduction of mechanism of material transport from linear plots of Eqs. (16) and (17)

	n	m	y
Surface diffusion D_s	7	4	No shrinkage
Evaporation/Condensation D_g	3	2	No shrinkage
Volume (bulk) diffusion D_l	5	3	0.4/0.5
Grain boundary diffusion D_b	5	3	0.3/0.33
Viscous/Plastic flow η	2	1	1

Fig. 25 Effect of sintering parameters (T – Temperature, P – Pressure, L – particle size) on densification. Reproduced from Kang, S.-J.L., 2005. Sintering, Densification, Grain Growth and Microstructure. Oxford: Elsevier Butterworth-Heinemann, by kind permission.

Uniaxial and isostatic hot pressings

The driving force leading to densification can be increased by external pressure application. The pressure can be uniaxially applied through punches on powdered sample inserted in a die (Hot Pressing) or isostatically applied through gas surrounding hermetically encapsulated powder compact (Hot Isostatic Pressing). In these cases, the driving force P due to the free energy difference across a curved grain boundary which has a few MPa range value is implemented by the external applied force which can reach 50 MPa (Hot Pressing) and 500 MPa (Hot Isostatic Pressing), respectively.

The application of an external pressure (σ_a) allows the acceleration of densification but also modifies the pore stability conditions as shown in Fig. 26 (Ewsuk and Messing, 1989) which allows to eliminate pores which by pressureless sintering would be stable or would have grown:

$$DF = \frac{2\gamma}{\kappa} + \sigma_a \quad \kappa = r \frac{\sin\left(90 - \frac{\psi}{2}\right)}{\sin\left(\frac{\theta}{2} - \frac{\psi}{2}\right)} \quad (18)$$

These two techniques allow theoretical density to be reached at lower temperatures than by pressureless sintering with limited grain growth.

Spark plasma sintering (SPS)

Spark plasma sintering (SPS) (Nygren and Shen, 2003), also known as field assisted sintering technique (FAST), uses an electrical current (DC, pulsed DC, or AC) which is passed through a conducting pressure die (graphite) and, if the material has reasonable electrical conductivity, through the ceramic itself. The die therefore acts as a heat source, so the sample is heated both internally and externally. Contrary to HIP, the SPS technique allows very rapid heating and cooling rates, very short holding times (a few minutes) and results in densification at much lower sintering temperatures, usually a few hundred degrees lower than for conventional sintering with restricted grain growth occurring only at the last sintering stage.

Flash sintering (FLASH)

This method is also referred to as the "Two-Electrode Experiment" (Raj *et al.*, 2011) and the process consists in heating the ceramic piece in a conventional furnace but applying an electrical current (DC or AC). The green sample is hung in the middle of the kiln by two platinum electrodes allowing the passage of current. At low fields (less than 40 V cm^{-1}), the sintering rate increase is

attributed to a reduction of the grain growth under an applied field; at higher fields, the specimens sinter almost instantaneously, as if in a flash, above a critical temperature (Cologna *et al.*, 2010).

Alternative Sintering Techniques

Microwave sintering

Microwave sintering allows reduction both in sintering temperature and time as there is direct coupling of the microwaves with electric dipoles within the ceramic (Binner and Vaidhyanathan, 2008). Full densification of alumina powders doped with Y_2O_3 and MgO within a few minutes and 250 degrees below the conventional sintering temperature, whereas the sintering trajectory showing grain size vs relative density was similar with both heating techniques (Fig. 27) (Brosnan *et al.*, 2003). These results were confirmed with a lower onset temperature of densification and smaller activation energy (Croquesel *et al.*, 2016).

The reasons for these specific microwave effects on sintering are still under debate with several hypothesis such as the possibility of a thermal effect related to local overheating at particle contacts under electric field, which could act on grain boundary diffusion or grain growth or the existence of a ponderomotive force induced by the electromagnetic field and acting on diffusion mechanisms (Croquesel *et al.*, 2016).

Cold sintering

This densification process requires the use of a few vol% fraction of a transport phase like water to facilitate the mass transfer between powder particles in combination with uniaxial force between 100 and 400 MPa. The mechanism is considered to be a multistep process similar to liquid phase sintering combining capillary forces and dissolution-solute supersaturation-precipitation phenomena (Guo *et al.*, 2019). Relative density levels between 70% and 99% can be reached with short holding time (a few tenth minutes) at modest temperatures 120–300°C depending on ceramic. First assays carried out on ZnO cold sintered with acetic acid as liquid transient phase between 70 and 305°C under 350 MPa have revealed a highly lower activation energy of grain growth compared to conventional sintering (Funahashi *et al.*, 2017).

Summary

Fabrication of ceramics includes a heat treatment of a powder compact to form a dense solid. This process of sintering involves matter transport to reduce porosity by diffusion of atoms in the vapor phase, in the liquid phase or in the solid state. Most mechanisms are activated thermally in order to overcome the potential barrier between the initial state of higher energy (porous powder compact) and the final state of lower energy (consolidated dense material). The chapter has outlined the processes involved in *Solid State Sintering* in the absence of any liquid phase and *"Liquid Phase Sintering"* in the presence of a small volume

percent of liquid phase. In all cases, the driving force for densification lies in the reduction of the surface energy resulting from the reduction in the interfacial area between gas and liquid/solid phases.

Fully dense ceramic materials with limited grain growth can be obtained by applying new technologies adding supplementary effects (application of external pressure and/or electric current) to fine grain size and well-dispersed powders. Moreover, these new techniques allow decrease of temperature and the duration of sintering and so are particularly promising for potential energy savings. Even if the grain growth phenomenon seems to be enhanced for the cold sintering, the huge sintering temperature decrease is promising for the development of faster and lower-energy processes and for new products not suffering high temperature treatment as ceramic-polymer composites.

Solid-State Sintering

John E Blendell, Purdue University, West Lafayette, IN, United States

Solid-state sintering is the bonding and densification of particles by the application of heat below the melting point of a material. During sintering, the free surface area of the compact decreases, and this is normally accompanied by an increase in the density, but it is possible for the compact to decrease its surface area and increase its cohesion without a perceptible increase in density. There will be changes in other properties of the compact, such as increased strength, an increase in electrical and thermal conductivity. For most applications, an increase in density is the desired result of sintering. As with any physical process, there must be a lowering of the total internal energy of the system to drive the process. In sintering this reduction in energy is the reduction in the total surface energy of the powder particles due to the replacement of surfaces by grain boundaries and due to coarsening. Overall, the reduction in internal energy is the difference in total surface energy of the powder compact and the remaining surface energy plus the total grain boundary energy of the sintered body.

Although sintering is the oldest method of forming materials from powders, an understanding of the processes occurring during heating of a powder compact is rather recent. Frenkel (1945), who was the first to propose a model for sintering, assumed that sintering occurred by the deformation of crystalline particles under the influence of surface tension, as would occur for amorphous materials such as glass. However, the predictions of this model did not agree with experimental results using crystalline particles. Kuczynski (1949) demonstrated that sintering occurs by diffusive processes. He proposed several models to describe the early stages of sintering for different transport mechanisms and diffusion paths. Coble (1961) developed models for the later stages of sintering for the case of lattice diffusion or grain boundary diffusion. Although later developments (see reviews by Exner, 1979; German, 1996; Handwerker *et al.*, 1989, 1990; Rahaman, 2008; Kang, 2005; Castro and van Benthem, 2013; Bordia *et al.*, 2017) have refined these basic ideas, the early models serve well to describe sintering processes. As sintering is a result of diffusive processes, two factors have the major influence on the rate of sintering: temperature (which controls the diffusion rate) and powder particle size (which controls the length scale for diffusion).

Sintering Stages

Sintering is conceptually divided into three stages: initial, intermediate, and final, expressing transitions in the connectivity of the particles within an ideal compact of single sized spheres. Within each stage, the pore shape change is well defined and the shrinkage of pores occurs with the pores maintaining a nearly constant shape. The initial stage refers to the growth of contacts or “necks” between the individual powder particles in the compact (Fig. 1). The radius of the necks grown in the initial stage ranges from zero to ~ 0.2 of the radius of the particles at which point the necks begin to overlap. In the intermediate stage, the pores are approximated as continuous channels coincident with the three-particle junctions (Fig. 2). The final stage begins when the pore channels break up into isolated pores located at the four-grain junctions (Fig. 3). This usually occurs when the density of the sample has increased to $\sim 92\%$ of the theoretical density of the material.

Driving Force for Sintering

During sintering the surface area of the powder compact is reduced. There are two processes that can cause this – coarsening and densification – shown schematically in Fig. 4. For an initial array of n spheres of size R the surface area is $n \cdot 0.4\pi R^2$. For coarsening of the spheres to a size $2R$, the number of spheres must decrease (to conserve mass) by a factor of eight and the surface area will be reduced by a factor of two. Thus, coarsening of the structure results in a reduction of the total surface energy. Notice that in this schematic there is no growth of the contacts between the particles and no decrease in the porosity of the sample. In contrast, if the spherical particles change their shape, the centers of the particles can move together and the volume of the sample will decrease. The surface area is completely converted to grain boundaries with an area of $n \cdot 2.15R^2$ (for a cubic array). The energy of a grain boundary is less than the energy of the two free surfaces that are eliminated (typically by about one order of magnitude), and thus the total energy is reduced. A reduction in total energy is a requirement for any process to occur.

The driving force for coarsening and densification arises from the pressure gradients at curved surfaces, and is conceptually described as, $\Delta P = \frac{2\gamma}{R}$, where γ is the surface energy and R is the radius of curvature.

Although both coarsening and densification result in a reduction in the surface area of the compact, coarsening does not induce densification but lowers the remaining driving force for densification and, as such, is usually an undesired process. Coarsening occurs if surface diffusion is dominating, while densification needs significant rates of grain boundary or volume diffusion. To determine which process dominates, it is necessary to determine the kinetics of these different diffusion mechanisms.

Fig. 1 Particles in the initial stage of sintering. Small “necks” can be seen connecting the particles.

Fig. 2 Structure showing the intermediate stage of sintering. Necks between particles have grown, resulting in a structure that contains continuous pore channels through the compact.

Initial Stage

The simplest model for initial stage sintering is the two-sphere model (Fig. 5), that contains all important features necessary for understanding sintering (Exner, 1979). The basic premise of the model is that matter is transported from regions of high chemical potential to regions of low chemical potential. In this model, the regions of high chemical potential are at the contact region (grain boundary) and along the convex surface of the sphere. The concave neck region is at a lower chemical potential relative to these areas. Matter can be transported to the neck region through the gas phase (by evaporation from the convex surface and condensation on the concave surface), by surface diffusion (from convex surface to concave surface), lattice diffusion (from either the convex surface or the grain boundary), or grain boundary diffusion. If the source of matter is the grain boundary, the two particle centers approach resulting in densification. If the source of matter is the convex particle surfaces, the two particles change shape without center approach (coarsening). Thus, in the initial stage of sintering, evaporation and condensation and surface diffusion result in coarsening, grain boundary diffusion results in densification and lattice diffusion can result in either, depending on the source of the matter transported.

Fig. 3 Polished surface of compact showing the final stage of sintering. Pores are isolated and generally located on the grain boundaries. Pore shape differences depending on location can be seen.

Fig. 4 Schematic of the competitive processes that occur during sintering. Densification results in surface area reduction, pore removal, and shrinkage of the compact. Coarsening results only in surface area reduction.

The driving force for transport during sintering is the difference in chemical concentration between the source of matter (particle surface or grain boundary) and the sink for matter (neck region). The concentrations are different due to the chemical potential differences that result from the curvature differences (Johnson, 1978). Along the particle surface the curvature changes from positive at the particle surface to negative at the neck region. Regions of positive curvature correspond to compressive stresses and will have a higher vapor pressure than a flat surface. Conversely, regions of negative curvature will have a tensile stress and a

Fig. 5 Two-particle model for initial-stage sintering. Transport of matter is from the particle surface or grain boundary to the neck region resulting in neck growth and densification.

lower vapor pressure than a flat surface. The vapor pressure difference tends to transport matter through the vapor phase into the neck region. The stress difference leads to transport by diffusion to the neck region. Both mechanisms will be active and the total neck growth will be the sum of the two processes. The tensile stress at the neck region is balanced by a compressive stress on the grain boundary. This compressive stress raises the concentration of atoms in the grain boundary region and the tensile stress lowers the concentration of atoms in the neck region. This concentration gradient leads to transport of matter from the grain boundary region to the neck region by grain boundary and lattice transport. In this case, there is densification of the compact.

Many different models have been proposed to describe the initial stage of sintering. In general, each model first assumes a geometry, determines the resulting chemical potential difference that is driving transport, calculates the mass flux based on the geometry and the concentration differences, and then relates the flux to the neck growth rate or the densification rate. If it is assumed that all the transport processes are independent and additive, the rate of neck growth in the initial state can be expressed as:

$$\frac{\partial x}{\partial t} = \frac{C_1 \gamma D_l R}{x^2} + \frac{C_2 \gamma D_b R^2}{x^5} + \frac{C_3 \gamma D_s R^2}{x^5} + \frac{C_4 \gamma p_0 R}{x}$$

where x is the radius of the neck, γ is the surface energy, R is the particle radius, C_i is a constant which takes into account the specific diffusion path and the geometry of the model, p_0 is the vapor pressure, and D_i is the diffusion coefficient for lattice (l), grain boundary (b), or surface (s) diffusion (Johnson, 1978).

Intermediate Stage

As neck growth proceeds there will be a transition in the pore structure to a system of tubular pores lying along the particle junctions; this is the intermediate stage. In this stage, the pore channels shrink in diameter until the geometry becomes unstable to fluctuations of the surface (Rayleigh instability). While the pore channels can shrink by surface diffusion, the path length for transport becomes very large and, thus, shrinkage is controlled by lattice or grain boundary diffusion (Rahaman, 2008). The geometry of the intermediate stage can be envisioned as a truncated octahedron (truncated octahedron) simple model of tubular pores intersected by 3 grain boundaries, Fig. 6(a). With transport from the grain boundary to the pores, Fig. 6(b), the densification rate for lattice diffusion control is

$$\frac{1}{\rho} \left(\frac{dp}{dt} \right) = \frac{10 D_l \gamma_{sv} \Omega}{\rho G^3 k T}$$

Fig. 6 Intermediate stage sintering model with pore channels being formed along the triple junctions.

When boundary diffusion is the rate controlling mechanism, the densification rate is

$$\frac{1}{\rho} \left(\frac{d\rho}{dt} \right) = \frac{4}{3} \left[\frac{D_{gb} \delta_{gb} \gamma_{sv} \Omega}{\rho (1 - \rho)^{1/3} G^4 kT} \right]$$

Modifications to this model have been developed to account for a realistic pore-boundary intersection that includes the dihedral angle. The size dependence, G^3 or G^4 , is not changed but additional terms are included to account for the more complicated geometry of the pore surface.

Final Stage

When the tubular pores have shrunk to the point where they are unstable, they will break up into isolated pores located at the grain junctions. This is the final stage of sintering and is the critical stage for most applications. It is during this stage that the properties of the compact reach the desired values. In the final stage, several factors must be considered in order to understand the process by which pores are eliminated. The driving force for shrinkage of the pores is the difference in concentration between the atoms on the curved surfaces of the pores and the grain boundaries. As the pores are isolated, surface diffusion can only change the shape of the pores. Shrinkage of the pores is controlled by grain boundary and lattice diffusion. For nearly spherical pores the flux of matter, J , to the pore is approximately:

$$J = K_i D_i \Delta c \left(\frac{r \mathfrak{R}}{\mathfrak{R} - r} \right)$$

where K is a geometric constant, D_i is either the lattice or grain boundary diffusion coefficient, Δc is the concentration difference, r is the radius of the pore, and $\mathfrak{R}$ is the effective source radius of matter being transported to the pore, roughly half the average distance to the neighboring pores.

Dihedral Angle Effect

In the discussion of the initial and intermediate stages it was assumed that the dihedral angle of the grain boundary with the pore surface is 180° , implying that the energy of the grain boundary is very much lower than the energy of the surface. As shown in Fig. 3, many pores have dihedral angles of less than 180° . For a pore on a grain boundary, the dihedral angle, ψ , is defined by the ratio of the grain boundary energy, γ_b , to the surface energy, γ_s , such that

$$\frac{\gamma_b}{\gamma_s} = 2 \cos\left(\frac{\psi}{2}\right)$$

Fig. 7 shows the shapes of pores for different values of the dihedral angle. The curvature of the pore surface increases as the dihedral angle increases, so the driving force for pore shrinkage also increases as the dihedral angle increases. When a pore is located on the junction of three or more grains, the curvature of the pore surface is determined by both the dihedral angle and the number of grains the pore contacts. For a three-sided pore and if $\psi = 60^\circ$ the pore will have straight sides and there will not be a driving force for shrinkage. Hence, this angle is a critical dihedral angle, ψ_{crit} for pore shrinkage. For a four-sided pore, $\psi_{crit} = 70.5^\circ$. The critical dihedral angle as a function of the number of surrounding grains is shown in Fig. 8 (Kingerly and Francois, 1967). Thus, when the dihedral angle is too low, pores will be stable in the structure and there will be a limiting density even though removal of the pores would lower the energy of the system. Ultimately, as grain growth occurs the number of grains intersecting the pore will decrease so that pores will become unstable and shrink. However, as the grain size increases, the diffusion distances increase and the shrinkage rate slows down, making pore removal a relatively slow process.

Fig. 7 Dihedral angle shows the effect of surface energy to grain boundary energy ratio on the shape of pores. Low dihedral angles result in elongated pores and high dihedral angles result in spherical pores.

Fig. 8 The stability of pores in the final stage of sintering as a function of the number of grains that the pore contacts. Pores with high numbers of sides will tend to be stable and remain in the structure.

Fig. 9 Typical temperature dependence of lattice, grain boundary and surface diffusion coefficients with temperature.

Pore Entrapment

The rate of pore shrinkage given above assumes that the pore is located on a grain boundary. During grain growth, pores can become entrapped inside a grain. In this case, lattice diffusion is the dominant transport mechanism for pore shrinkage and the diffusion distance is the pore–boundary separation distance. Practically, such pores cannot be eliminated during sintering. Pores can become trapped inside a grain if grain growth occurs during final stage sintering. In the intermediate stage of sintering, large pore channels inhibit grain growth due to the strong drag effect of pores on grain boundary motion. As the densification continues and the final stage of sintering is reached, the pores shrink and their drag effect on grain boundary motion decreases until eventually grain boundaries detach from the pores and grain growth occurs and pores become entrapped in the grains.

For isolated pores (final stage of sintering) on grain boundaries that contain a gas phase that is insoluble in the lattice, shrinkage will be limited by the rate at which the gas can diffuse to the surface of the sample. This can also lead to a limiting density, but changing the atmosphere during sintering can minimize the effect.

Effects of the Heating Rate

The mass transfer mechanisms during sintering have different temperature dependences due to different thermal activation (Fig. 9). Usually, surface diffusion dominates the sintering process at low temperatures, grain boundary diffusion at intermediate temperatures and volume diffusion at high temperatures. For some materials, some of these processes play no significant role, and some might have additional mass transfer processes as e.g., evaporation and condensation at very high temperatures. As surface diffusion does not result in densification but in coarsening and lowers the driving force for densification, fast heating rates are beneficial for densification as less time is available for surface diffusion coarsening. This rationale resulted in the emergence of the fast firing technique: powder compacts are inserted in a furnace that is pre-heated to the sintering temperature to achieve the fastest possible heating rates. Other techniques that utilize fast heating rates to improve densification are SPS and flash sintering (see below) and laser flash sintering.

Effects of Mechanical Pressure

If a mechanical pressure P_a is applied to the system by external means, this pressure adds to the driving force for sintering. However, as the powder compact is not fully dense, the pressure acts on the particle contact area resulting in a higher pressure in the sintering neck area. The effective pressure ΔP_{eff} is higher by a stress intensification factor ϕ :

$$\Delta P_e = \phi P_a$$

The stress intensification factor accounts for the size of the sintering neck relative to the particle size. Usually, it is assumed that ϕ is inversely proportional to the relative density ρ . The modified driving force for sintering is the sum of the two pressures,

$$\Delta P = \frac{2\gamma}{R} + \phi P_a$$

Using this modified driving force for sintering, the shrinkage rate can be obtained for the different diffusion mechanisms and sintering stages as shown in Table 1. Note that for $P_a = 0$ the equations reduce to the pressureless densification rates.

In general, applying a mechanical pressure is useful for materials where high densities are not achieved with pressure-less sintering as e.g., classically the case for refractory or transparent materials. There are different ways of applying mechanical pressure to a powder compact. Uniaxial pressures are applied in hot pressing and spark plasma sintering (SPS).

Table 1 Densification rate $\frac{1}{\rho} \frac{d\rho}{dt}$ for pressure assisted sintering with different mass transport mechanisms. D is the respective diffusion coefficient (l: lattice, gb: grain boundary), Ω the molecular volume, G the grain size, k the Boltzmann constant, γ_{sv} the surface energy, r the pore radius

Mechanism	Intermediate stage	Final stage
Lattice diffusion	$\frac{1}{\rho} \frac{d\rho}{dt} = \frac{40}{3} \left(\frac{D_l \Omega}{G^2 kT} \right) \left(P_a \phi + \frac{\gamma_{sv}}{r} \right)$	$\frac{1}{\rho} \frac{d\rho}{dt} = \frac{40}{3} \left(\frac{D_l \Omega}{G^2 kT} \right) \left(P_a \phi + \frac{2\gamma_{sv}}{r} \right)$
Grain boundary diffusion	$\frac{1}{\rho} \frac{d\rho}{dt} = \frac{95}{2} \left(\frac{D_{gb} \Omega}{G^3 kT} \right) \left(P_a \phi + \frac{\gamma_{sv}}{r} \right)$	$\frac{1}{\rho} \frac{d\rho}{dt} = \frac{15}{2} \left(\frac{D_{gb} \Omega}{G^3 kT} \right) \left(P_a \phi + \frac{2\gamma_{sv}}{r} \right)$
Dislocation motion ^a	$\frac{1}{\rho} \frac{d\rho}{dt} = A \left(\frac{D_{\mu b}}{kT} \right) \left(\frac{P_a \phi}{\mu} \right)^n$	$\frac{1}{\rho} \frac{d\rho}{dt} = B \left(\frac{D_{\mu b}}{kT} \right) \left(\frac{P_a \phi}{\mu} \right)^n$

^aA and B are numerical constants; n is an exponent that depends on the mechanism of dislocation motion.

In hot pressing, a punch-die combination (typically graphite) is used in a vacuum furnace and with a load frame. Heating rates are limited by the furnace (typically <50 K/min). Maximum pressures and temperatures are limited by the heater and die materials and are in the order of 2200°C and 100 MPa.

Spark plasma sintering (SPS) is similar to hot pressing in that a uniaxial pressure is applied to a graphite-based punch-die combination. However, the punch-die combination is heated directly by an electrical current resulting from a voltage between the two rams of the press. While maximum pressures and temperatures are comparable to hot pressing, much higher heating rates (more than 200K/min) can be used, resulting in less time for coarsening during heating as discussed above. SPS sintering is used for refractory materials, but also for applications where a fine-grained microstructure is needed.

Hot isostatic pressing (HIP) uses gas pressure in an autoclave. Mostly, nitrogen or argon is used along with graphite heaters. Typical maximum temperatures and pressures are 2200°C and 400 MPa. Note that this method only densifies the closed porosity as, for open porosity, the pressure does not load the particle contact area. This requires a pre-sintering to about 94% relative density by conventional sintering.

Applying a mechanical pressure to closed porosity can result in a build-up of high gas pressure in the remaining porosity as it shrinks. This pressure can result in pore swelling and de-sintering if high temperatures are subsequently applied without pressure e.g., during pressureless cooling after sintering or during a high-temperature application.

Effects of Electric Fields and Currents

The impact of electric fields and currents on sintering have been observed to greatly affect the densification rate as observed recently in flash sintering. For flash sintering, the powder compact is contacted by electrodes and a voltage is applied during the heating ramp. If the conductivity of the powder compact increases with increasing temperature, an increasing current flow occurs resulting in a direct heating of the sample, until a thermal runaway event occurs. The electric current during flash sintering results in Joule heating of the powder compact and this can result in very high heating rates, many hundred K/min that are beneficial for densification. While SPS sintering does not involve a thermal run-away of the sample, electric currents might flow through the powder compact if its conductivity is higher than the surrounding graphite die.

The impact of the electric field itself is controversial and still being investigated. While the electric field is not relevant to the curvature driving force for sintering, it can result in electromigration of charged defects and result in a microstructure gradient and a variation of properties along the electric field. Electric fields can result in the nucleation of additional defects (e.g., point defects and dislocations) that may increase transport. Electrolytic decomposition at the electrodes is another effect that can occur due to electric field assisted sintering.

Effects of Constraints

Mechanical constraints inhibit the shrinkage of a powder compact during sintering and can result in anisotropic densification and cracking. Such constraints occur when a powder layer is sintered on a dense substrate or if a composite with different densification rates are co-sintered. In general, the constraint results in a lower densification rate:

$$\left(\frac{\dot{\rho}}{\rho} \right)_{\text{constraint}} = \frac{1+v}{1-v} \times \frac{1}{3} \times \left(\frac{\dot{\rho}}{\rho} \right)_{\text{free}}$$

with the shrinkage rate $(\dot{\rho}/\rho)$, the relative density ρ and the viscous Poisson's ratio v . Constraints on sintering frequently result in residual porosity, delamination and sintering distortion due to mechanical stresses developed at the constraint.

Summary

This chapter is a summary of the basic ideas of solid-state sintering. Many of the features of sintering are well understood. It is clear from the modeling and experiments that particle size is a dominant factor in controlling sintering rates. Other important

parameters are the transport mechanisms that dominate sintering in a given case, heating rates and mechanical pressures. Along with an emerging understanding of these parameters, different sintering techniques are being developed, as e.g., SPS sintering which utilizes fast heating rates and a mechanical load to obtain fast densification.

Liquid Phase Sintering: Fundamentals

Suk-Joong L. Kang, Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, South Korea

© 2021 Elsevier Inc. All rights reserved.

When a powder mixture compact of at least two different components is heated up above the eutectic temperature of the components or the melting temperature of a component with a low melting point, a liquid phase forms and sintering proceeds in the presence of the liquid phase. This sintering process is called liquid phase sintering (LPS) as long as the liquid phase is retained during the whole period of sintering time. (If the liquid phase disappears during sintering, the process is called transient liquid phase sintering. We will not consider this case in this chapter).

The liquid phase sintering technique has been used for several thousand years for fabricating traditional ceramics as an art in pottery, bricks and porcelains. This technique is now widely utilized as an essential technique for fabricating modern ceramic materials and components, such as Al_2O_3 -, ZnO -, TiO_2 -, BaTiO_3 -, $\text{Pb}(\text{Zr,Ti})\text{O}_3$ -, $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ -, $(\text{K}_{0.5}\text{Na}_{0.5})\text{NbO}_3$ -, $(\text{Na}_{0.5}\text{Bi}_{0.5})\text{TiO}_3$ -, SiC -, Si_3N_4 -, and SiAlON -based ceramics for structural, functional and electronic applications.

Scientific studies on sintering, including LPS, started in the late 1940s and early 1950s (Kang, 2005). Several models (Cannon and Lenel, 1953; Kwon and Yoon, 1981; Kang *et al.*, 1991; Svoboda *et al.*, 1996) and theories (Kingery, 1959; Kwon, 1996; Mortensen, 1997; Lee and Kang, 1998) have been developed. The developed models are basically for different stages, where a dominant mechanism was postulated for each stage. For example, a classical model (Cannon and Lenel, 1953) suggested three stages of densification: (1) particle rearrangement due to liquid flow at the early stage, (2) contact flattening between particles by dissolution and precipitation of a solid phase through the liquid, and (3) solid-state sintering between particles. Later, filling pores with liquid was another mechanism of densification (Kwon and Yoon, 1981; Kang *et al.*, 1991). The pore filling stage has sometimes been presumed to be the last stage of LPS.

The available models and theories of LPS concern different roles of the liquid in the compact: (1) the provision of a diffusion path of atoms dissolved from particles and (2) capillary action of the liquid that leads its flow. The former plays a passive role for densification as well as grain growth and the latter an active role for densification. If these two roles of liquid are absent, the sintering behavior and kinetics must be similar to those in solid-state sintering. In this chapter, we will describe these two different roles of liquid in relation to densification and grain growth.

General Phenomena of Liquid Phase Sintering

For LPS to proceed, the solid must be soluble in the liquid and the wetting angle must be low. If the solubility is negligible, the transport of atoms through the liquid and its contribution to densification and grain growth must also be negligible. If the wetting angle is large, densification will not proceed and swelling of the compact or sweating of liquid at the compact surface can occur.

Fig. 1 is an example of microstructural evolution during LPS (Park *et al.*, 1989). (Although the system is metallic, the figure clearly shows the typical evolution of microstructure during LPS.) Considerable densification as well as remarkable grain growth took place during the LPS. At the LPS temperature of this W-Ni-Fe sample, such a considerable sintering is impossible for a W powder compact (with a melting point of 3422°C) without a liquid phase in the sample. When a liquid phase forms in a powder compact, atom transport through the liquid and mass flow of the liquid itself can take place. The former can induce densification and grain growth, while the latter only densification.

For densification during LPS, a few models and theories have been developed for different stages. They include particle rearrangement with the appearance of a liquid, contact flattening in the presence of a liquid film at the areas of particle contact, and liquid filling of pores. For grain growth, basically two models are available, a diffusion control model and a mixed (either diffusion or interface reaction) control model. We will describe and discuss the mechanisms of densification and then the mechanisms of grain growth and related microstructural evolution.

Densification During Liquid Phase Sintering

Densification during LPS is a process for developing a dense and equilibrium microstructure for a given volume fraction of liquid and given sizes of particles. In a fully dense sample with the minimum total interfacial energy, the liquid is in a hydrostatic pressure and no excess pressure is present between particles. There are a few processes that can contribute to densification and obtaining an equilibrium microstructure. They include (1) a change in powder packing (particle rearrangement) due to liquid flow at the moment of liquid formation, (2) atom transport from the contact area to the off-contact area, and (3) liquid filling of pores.

Particle Rearrangement

When a liquid phase forms, liquid redistribution takes place because of uneven capillary forces around particles. For a system with a low wetting angle, liquid penetration between solid particles occurs as the sizes of the capillaries at the contact and neck regions

Fig. 1 Microstructural change during liquid phase sintering of 98W(5 μ m)–1Ni–1Fe (wt%) at 1460°C for various periods of time. Circles indicate liquid pockets formed by pore filling. Reproduced from Park, J.K., Kang, S.-J.L., Eun, K.Y., Yoon, D.Y., 1989. The microstructural change during liquid phase sintering. *Metall. Trans. A* 20, 837–845.

are, in general, smaller than that of the bulk liquid formed between particles. This process is similar to the flow of water in a glass tube with two different diameters from the region with a large diameter to that with a small diameter. During liquid flow (penetration) between particles, the particles can move along with the flow (particle rearrangement). The particle rearrangement is possible only for systems with no solid bonding between particles at the moment of liquid formation and those with the dihedral angle of zero degrees. If grain boundaries form during heating to the liquid phase sintering temperature and the dihedral angle is non-zero, such as the case in [Fig. 1\(a\)](#), particle rearrangement is impossible even right after the liquid formation.

Assuming that each particle is surrounded by liquid, it was suggested that particle rearrangement during LPS could be modeled as a viscous flow ([Kingery, 1959](#); [Kwon, 1996](#)) and could considerably enhance densification. A mass flow of a solid-liquid mixture, however, seems to be possible only in systems with a dihedral angle of zero degrees and pores much larger than particles, as in a previous experiment ([Kang et al., 1984](#)). If the pore size is comparable with the particle size and the liquid volume fraction is not sufficient for filling all the pores, only a local rearrangement of particles would be possible. [Fig. 2](#) ([Lee et al., 1999](#)) shows simulated microstructural evolution after liquid formation in a two-dimensional compact of spherical particles with a coating of a low melting component. The microstructures show that overall densification occurred, forming fairly dense regions, and at the same time, the size of relatively large original pores increased due to local rearrangement and densification. Although this simulation study as well as previous studies ([Kingery, 1959](#); [Kwon, 1996](#)) suggest the possibility of considerable contribution of particle rearrangement to densification, its contribution, however, may be inconsiderable in real systems. The literature has not, so far, reported a considerable enhancement of densification for an expected time period of liquid flow.

Contact Flattening Versus Pore Filling

Contact flattening

After the formation and redistribution of a liquid, the microstructure of a powder compact generally consists of fairly dense agglomerated (clustered) regions of particles and liquid, and pores distributed between the agglomerated regions, as shown in [Fig. 1\(a\)](#). In such a sample with agglomerated regions, fast transport of atoms can occur through the liquid phase via dissolution and precipitation of solid among grains.

At the early stage of LPS, a compressive force can be exerted between particles in contact with one another due to the capillary pressure and surface tension of the liquid. Material can be transported from the contact area to an off-contact area (this process is called contact flattening), which can contribute to grain shape accommodation, and to densification and shrinkage. This is the basic idea of the classical contact flattening theory of LPS ([Kingery, 1959](#)). Under the assumption that the microstructure was

Fig. 2 Simulated microstructural evolution of a two-dimensional particle array with holding time for liquid viscosity of $1 \text{ mPa} \cdot \text{s}$: (a) 0.08 , (b) 0.2 , (c) 0.6 , and (d) $3 \mu\text{s}$. Reproduced from Lee, S.-M., Chaix, J.-M., Martin, C.L., Allibert, C.H., Kang, S.-J.L., 1999. Computer simulation of particle rearrangement in the presence of liquid. *Metals Mater.* 5, 197–203.

simplified as mono-sized particles with a dihedral angle of zero degrees and uniformly distributed pores at the neck of the particles, the theory claims a continuous and considerable contribution of contact flattening to densification until the complete elimination of pores. The theory, however, much overestimates the material removal from the contact area because the driving force for the material transport quickly decreases with grain shape accommodation.

When the grains attain their equilibrium shape with the minimum total interfacial energy for a given liquid volume fraction around the grains, the driving force for contact flattening disappears in an agglomerate. Thus, there is no shrinkage of pores that are located around the agglomerate. If we ignore the shape of grains at the surface, the microstructure of a dense agglomerate with grains of an equilibrium shape must be the same as that of a dense bulk material with the same liquid volume fraction. The only difference is the size of the sample and the size of pores. The pore size is infinite for a bulk sample, while the pore size is finite for an agglomerate.

For an agglomerated region of particles (grains) and liquid, grain shape accommodation can occur not only by the removal of solid from the contact area but also by growth of grains. A model calculation (Lee and Kang, 2001) showed that the contribution of grain growth to grain shape accommodation is more significant than that of contact flattening. Therefore, the driving force for contact flattening can quickly decrease and disappear. As a result, the contribution of contact flattening to densification is much less than that predicted by the contact flattening theory.

For the hypothesized microstructure of the contact flattening theory, where grain growth does not take place, the contribution of contact flattening can be significant for systems with a zero dihedral angle until liquid filling of pores takes place (Kang, 2005). In real systems, however, it is not possible that no grain growth would occur in an LPS sample. In addition, for systems with a non-zero dihedral angle, where the material transport from the contact area occurs in a solid state, the con-

Fig. 3 Schematic changes in the liquid meniscus radius at the sample surface and at a pore surface during grain growth. (a) before liquid filling of the pore (stable state of the pore), (b) critical moment for pore filling (complete wetting of the pore surface) and (c) liquid flow into the pore (pore filling) immediately after the critical moment. P : pressure in the liquid; ρ : the radius of liquid meniscus ($\rho_1 < \rho_2$, $\rho_2 \lesssim \rho_3$). Reproduced from Kang, S.-J.L., Greil, P., Mitomo, M., Moon, J.-H., 1989. Elimination of large pores during gas-pressure sintering of β' -Sialon. *J. Am. Ceram. Soc.* 72, 1166–1169.

tribution of contact flattening must be almost nil. It appears that densification by contact flattening is insignificant in real systems, in particular those with a non-zero dihedral angle.

Pore filling

It was observed in the early 1980s that pores with a much bigger size than grains were eliminated by liquid flowing into them (liquid filling of pores) (Kwon and Yoon, 1981). Several subsequent experiments supported the pore filling to be the major mechanism of densification during LPS, irrespective of the shape and size of pores (Kang *et al.*, 1984; Park *et al.*, 1989). The pore filling model and theory were developed in the 1990s (Kang *et al.*, 1991; Lee and Kang, 1998).

Pore filling is a result of a liquid flow in a sample, as in the case of liquid penetration among particles. When the driving force for contact flattening disappears with grain shape accommodation, the pores around a dense solid-liquid agglomerate become stable. As long as a pore is stable, no matter the size, the microstructure of the dense region with an equilibrium microstructure will evolve in a self-similar manner. Whenever the pressure in a liquid becomes uneven, liquid flows from a region with a high pressure to a region with a low pressure. Such a situation can arise during growth of grains.

Fig. 3 (Kang *et al.*, 1989) schematically depicts the growth of grains and a related change in liquid meniscus radius at the sample surface and at a pore surface. If the gas pressure in the pores is the same as that outside the sample, the radius of the liquid meniscus is the same everywhere, including the sample surface and the pore surface because of the hydrostatic pressure in the liquid. As grains grow, the radius of the liquid meniscus increases in proportion because the microstructure in a dense body evolves self-similarly. When the radius of the liquid meniscus becomes the same as the radius of a pore (in the case of a wetting angle of zero degrees), the pore surface is completely wetted by the liquid (**Fig. 3(b)**). With further growth of grains (**Fig. 3(c)**), the radius of the liquid meniscus at the sample surface and other unwetted pore surfaces increases further. However, at the surface of the just wetted pore, the meniscus radius is limited to the pore radius. A pressure imbalance arises in the liquid and liquid flows into the wetted pores from all the densified region (pore filling). The critical radius of the liquid meniscus for liquid filling of pores is proportional to the pore size, which is, in turn, proportional to the grain size. Therefore, liquid filling occurs in temporal sequence: small pores earlier and large pores later. Experimental observations, including that in **Fig. 1**, show that small pores disappear earlier and large pores remain intact for a longer time, which supports the prediction of the pore filling model (Kang *et al.*, 1991).

Based on the understanding of the pore filling process, the pore filling theory was developed, which predicts the effects of various processing parameters, including pore size and distribution, liquid volume fraction, wetting and dihedral angle, and entrapped insoluble gases (Lee and Kang, 1998). As the densification by pore filling is induced by grain growth (grain growth-induced densification), its kinetics is dependent on the grain growth kinetics. If grain growth kinetics follows a cubic law, the densification kinetics with respect to scale also follows a cubic law. It is also possible to describe the microstructural evolution on a relative density versus grain size plane, for example, as shown in **Fig. 4** (Lee and Kang, 2005). It appears that pore filling, which is a result of grain growth, is the dominant mechanism of densification during LPS.

(Ed.), *Microstructural Design of Advanced Engineering Materials*. Weinheim:Wiley-VCH Verlag GmbH & Co.

Grain Growth During Liquid Phase Sintering

Grain growth (coarsening) in a matrix, either a liquid or a solid, is called Ostwald ripening. Ostwald ripening is the result of growth and shrinkage of individual single crystal grains in a matrix. Therefore, crystal growth and dissolution theories (Hirth and Pound, 1963; Peteves and Abbaschian, 1991) can be useful for understanding grain growth behavior during LPS.

Growth of a single crystal is the result of serial processes of diffusion of atoms through the matrix towards the crystal and attachment (interface reactions) of the transported atoms at the surface of the growing single crystal. According to the crystal growth theories, in the growth of a spherical crystal, which has an enormous number of surface defects, there is no energy increase with atom attachment, and the interface reaction kinetics is much faster than the diffusion of atoms through the liquid. Therefore, the growth rate is linearly proportional to the driving force for crystal growth (diffusion), as schematically shown in Fig. 5 (Kang *et al.*, 2013) as a dashed straight line.

On the other hand, for a faceted polyhedral crystal with atomically ordered surfaces, the attachment of a transported atom (interface reaction) increases the surface energy because it has an energy barrier for atom attachment. If the growth of a faceted single crystal is governed by the formation of a two-dimensional nucleus (2DN) and its growth on a flat surface, the interface reaction rate is expressed as an exponential function of the driving force for crystal growth, as schematically shown in Fig. 5 (Kang *et al.*, 2013) as a

dotted curve. If there are surface defects, for example screw dislocations on the surface, the kinetics is enhanced and expressed to be proportional to the square of the driving force. Therefore, for the growth of a faceted crystal, there is a range where interface kinetics is slower than diffusion kinetics and another range where interface kinetics is faster than diffusion kinetics. (Note that the dissolution rate is always linearly proportional to the driving force for dissolution because each corner of a faceted crystal acts as a dissolution source without an energy barrier and multilayer dissolution can occur (Jung *et al.*, 2009)). As the slower process governs the overall kinetics in serial processes, the interface reaction is the governing process for a small driving force while the diffusion is the governing process for a large driving force, as schematically shown in Fig. 5 as thick solid lines. A critical driving force is present for the transition from the interface reaction control to the diffusion control. The critical driving force is affected by the faceting tendency of the crystal; it increases with an increasing faceting tendency.

In a sample being sintered, where numerous grains are present, each grain has its own driving force for growth or dissolution relative to the grain that neither grows nor shrinks at the moment of observation. Therefore, there is a range of driving force in a sample as schematically shown in Fig. 5. The maximum driving force for growth is for the largest grain in the sample.

For a sample with spherical grains, the growth rate of grains is linearly proportional to the driving force. For such a system, the well-known Lifshitz-Slyozov-Wagner (LSW) theory (Lifshitz and Slyozov, 1961; Wagner, 1961) and related theories (German and Olevsky, 1998) predict normal grain growth with an invariable distribution of grain sizes relative to the average grain size. A cubic law, where the cube of the average grain size is proportional to the annealing time, is valid for a system with spherical grains. Many experimental observations confirm normal grain growth in systems with spherical grains.

In a sample with faceted grains, the growth rate of grains whose driving forces are smaller than a critical value is insignificant, in particular for the growth by 2DN. On the other hand, the growth rate of grains whose driving forces are larger than the critical value is considerable and linearly proportional to the driving force for growth. The growth of a grain is controlled either by interface reaction or diffusion (mixed control). The grain growth behavior in a faceted system is then governed by the relative value between the maximum driving force for the largest grain in the sample, $\Delta g_{\max}$, and the critical driving force for diffusion control, Δg_c . Based on this understanding, Kang and his coworkers (Jung *et al.*, 2009; Kang *et al.*, 2009) deduced the mixed mechanism principle of microstructural evolution. The principle predicts various types of time dependent grain growth behavior in terms of the relative value between $\Delta g_{\max}$ and Δg_c :

- (1) $\Delta g_c = 0$: Normal grain growth (NGG)
- (2) $0 < \Delta g_c \ll \Delta g_{\max}$: Pseudo-normal grain growth (PNGG)
- (3) $0 < \Delta g_c \lesssim \Delta g_{\max}$: Abnormal grain growth (AGG)
- (4) $\Delta g_{\max} \ll \Delta g_c$: Stagnant grain growth (SGG)

From the principle, they also deduced some strategies for suppressing AGG (Fisher and Kang, 2018). The validity and the generality of the mixed mechanism principle seem to be well supported by a large number of experiments for metals as well as ceramics (Kang *et al.*, 2013).

As densification by pore filling is induced by grain growth, even AGG can be beneficial for densification. A beneficial effect of AGG for densification was observed in a few cemented carbide systems. It seems that densification in a faceted system occurs mostly via pore filling with grain growth.

Concluding Remarks

Densification during liquid phase sintering is a process for developing an equilibrium microstructure with the minimum total interfacial energy for a given grain size and a given liquid volume fraction. During this process grain growth also takes place. In LPS, the role of liquid is critical for both densification and grain growth. A liquid phase provides a diffusion medium of atoms dissolved from grains and also flows by itself during sintering. The former contributes mostly to grain growth (Ostwald ripening) but marginally to densification (contact flattening). The flow of liquid right after the formation of a liquid phase can rearrange particles, of which the contribution to densification seems to be insignificant. Most densification can be achieved by liquid filling of pores, which is induced by grain growth. The pore filling theory predicts the effects of various processing parameters on densification by pore filling.

Various types of microstructures appear during LPS. The conventional Ostwald ripening theory (the LSW theory), which predicts only normal grain growth, is valid for systems with spherical grains. For systems with (even partially) faceted grains, grain growth behavior varies with sintering time. Based on the crystal growth theories, the mixed control theory of grain growth and the mixed mechanism principle of microstructural evolution were developed. Many experimental observations for metals as well as ceramics supported the validity and the generality of the microstructural evolution principle.

Viscous Sintering

George W Scherer, Princeton University, Princeton, NJ, United States

© 2021 Elsevier Inc. All rights reserved.

This is an update of GW Scherer, Viscous Sintering, In: The Encyclopedia of Materials: Science and Technology, Second Edition, Elsevier Inc., 2001, doi:10.1016/B0-08-043152-6/01725-3.

Viscous Sintering

Viscous sintering is a process by which a noncrystalline material reduces its surface area, and thereby reduces its free energy. The process is illustrated in Fig. 1, which shows spherical particles of glass coalescing, just as raindrops on a window merge to reduce their surface area. In contrast to crystalline materials, where sintering involves diffusion of vacancies in the crystal lattice, noncrystalline materials sinter by viscous flow. The rate of viscous sintering is found to be insensitive to the details of the microstructure of the material, so the rate of densification can be estimated given only the viscosity and surface tension of the material and its average pore size. In practice, materials are often constrained during sintering; for example, the densification rate of a film is reduced by its attachment to a substrate that does not shrink as the film does. The sintering rate can be calculated in such cases, if the mechanical properties of the porous material are known. An important type of constraint is crystallinity, because crystalline inclusions sinter more slowly than glass, so they retard the overall shrink-age.

Sintering Models

The theoretical basis for viscous sintering was established by Frenkel (1945), who argued that the energy needed to drive viscous flow is provided by reducing the surface area of the body (thereby releasing the surface energy); therefore, the rate of sintering can be found by equating those two energies. To calculate the energy that is dissipated by viscous flow as a certain amount of surface area is eliminated, it is necessary to choose a particular microstructural model. Frenkel analyzed the coalescence of spheres, as in Fig. 1. That is a surprisingly difficult problem to solve exactly, because the region of contact between particles has a complicated shape, so Frenkel had to make severe simplifying assumptions about the pattern of viscous flow. The distance, L , between the centers of a pair of sintering spheres was found to decrease linearly with time, t , according to

$$\frac{L[0] - L[t]}{L[0]} = \frac{3 \gamma r}{8 \eta a} \quad (1)$$

where γ is the surface tension, η is the viscosity, and a is the initial radius of the spheres.

This linear shrinkage rate has been experimentally verified. A detailed numerical simulation of the flow within sintering spheres was performed by Jagota and Dawson (1990). They showed that Frenkel's assumptions are poor, but his result is rather close to the exact solution, evidently as a result of offsetting errors.

The next major step in the analysis of viscous sintering was by Mackenzie and Shuttleworth (1949), who calculated the rate of shrinkage of a spherical shell. This is an excellent model for the final stages of sintering, when the pores become isolated, and it is relatively easy mathematically, because the spherical shape of the shell is preserved as the shell contracts. They found that the volume fraction of solids (also called the *relative density*), ρ , varies with time as

Fig. 1 Coalescence of spherical particles of glass. Reproduced from Exner, H.E., 1979. Principles of single phase sintering. In: Reviews on Powder Metallurgy and Physical Ceramics – 1/1–4, pp. 1–251. Freund Publishing House.

$$\frac{\gamma n^{1/3} t}{\eta} = f[\rho[t]] - f[\rho[0]] \quad (2)$$

where

$$f[\rho] = -\frac{2}{3} \left(\frac{3}{4\pi} \right)^{1/3} \left(\sqrt{3} \tan^{-1} \left[\frac{2(1/\rho - 1)^{1/3} - 1}{\sqrt{3}} \right] + \frac{3}{2} \log \left[(1 - \rho)^{1/3} + \rho^{1/3} \right] \right) \quad (3)$$

The dimensionless time axis is $\gamma n^{1/3} t / \eta$, where n is the number of pores per unit volume of solid; in this case, n is 1 divided by the volume of solid in the shell (which is independent of time). The shape of the densification curve is indicated in **Fig. 2**.

To compare this result with Frenkel's, consider a simple cubic packing of spheres where each unit cell contains one particle (1/8 of each of the 8 particles at the corners of the cell) and has one pore in the center. For that structure, there is one pore per particle, so $n = 1/(4 \pi a^3/3)$, and since $L(t)/L(0) = \rho(0)^{1/3}/\rho(t)^{1/3}$, **Eq. (1)** can be written as

$$\frac{\gamma n^{1/3} t}{\eta} = \frac{8}{3} \left(\frac{3}{4\pi} \right)^{1/3} \left(1 - \left(\frac{\rho[0]}{\rho[t]} \right)^{1/3} \right) \quad (4)$$

In view of the geometrical assumptions made by Frenkel, **Eq. (4)** should only apply to the first 5%–10% of linear shrinkage, while the particles are nearly spherical. For the simple cubic packing, $\rho(0) = 0.52$, so the range of applicability would include densities up to ~ 0.65 . As indicated by the dashed curve in **Fig. 2**, **Eq. (4)** agrees well with the MS model, **Eq. (2)**, for $0.52 \leq \rho \leq 0.7$, so these models predict almost identical sintering kinetics, even though they are based on completely different geometries.

Frenkel's model is expected to apply only at the beginning of sintering, whereas the MS model only applies near the end of sintering, after the pores have become isolated bubbles. For bodies with low initial densities, such as gels or vapor-deposited optical waveguide preforms, there is a large increase in ρ that is not realistically described by either model. For such materials, **Scherer (1977, 1991)** introduced a model where the solid phase is represented by cylindrical rods joined at nodes to create a network. The rate of densification for a network of any shape (e.g., cubic, octahedral, tetrahedral) is found to obey the following equation:

$$\frac{1}{\rho} \frac{d\rho}{dt} = \frac{\gamma S \rho_s}{2 \eta} \quad (5)$$

where S is the specific surface area and ρ_s is the density of the solid phase. The predicted sintering rate for a cubic array of cylinders is indicated by the dotted curve in **Fig. 2**, and it is seen to agree well with the other models. Thus, the theoretical analyses predict similar sintering kinetics for widely different geometries. Experimental studies (see review in **Brinker and Scherer, 1990**) verify that the sintering rate of non-crystalline particles follows the curves predicted by the MS or network models.

Fig. 2 Relative density ρ versus time for spheres (Frenkel), spherical shell (M-S), and cubic network (Cubic), calculated assuming an initial density of $\rho(0) = \pi/6 (=0.52)$ as for a simple cubic packing of spheres. Frenkel's model is only expected to apply to the early stage of sintering (in this case, up to $\rho \leq 0.65$). The curve for the cubic network terminates at $\rho \approx 0.94$, where the pores become isolated; beyond that point, the MS model applies.

Factors Affecting Sintering Rate

If the initial density of the body lies between $0.2 < \rho < 0.8$, which covers the range of practical interest, then Fig. 2 shows that the time needed to complete sintering, t_s , is approximately $\gamma n^{1/3} t_s/\eta \approx 1$, or

$$t_s \approx \frac{\eta}{\gamma n^{1/3}} \approx \frac{1.6 \eta a}{\gamma} \quad (6)$$

where the second equality applies for the simple cubic packing of spheres. Eq. (6) indicates that smaller particles sinter faster; Eq. (5) leads to the same conclusion, since S is inversely proportional to particle size ($S = 2/(a \rho_s)$ for cylinders and $S = 3/(a \rho_s)$ for spheres). For crystalline materials, t_s is much more sensitive to particle size, varying as a^3 or a^4 . The sintering rate increases (or, t_s decreases) as the surface tension increases, because the surface energy is the driving force for the process. The dependence of γ on temperature and composition is weak for liquids; its value is on the order of 0.1 J/m^2 for organics and $0.25\text{--}0.4 \text{ J/m}^2$ for oxide liquids. In contrast, the viscosity is extremely sensitive to both temperature and composition, so the sintering rate can be drastically reduced by raising the temperature (for glass-forming silicate liquids, t_s drops an order of magnitude for an increase of $\sim 100^\circ\text{C}$). The viscosity of oxides is strongly reduced by hydroxyl (OH) groups, so the sintering rate is greatly accelerated by moisture in the air; for silica, the sintering rate is an order of magnitude faster in air than in a dry gas, such as helium (Brinker and Scherer, 1990). The solid phase of a gel contains large amounts of OH that is gradually lost during sintering, resulting in continuously increasing viscosity and decreasing densification rate; consequently, it is advantageous to use a constant heating rate when sintering a gel, so that the effect on η of rising temperature offsets the loss of OH (Brinker and Scherer, 1990).

Sintering Under Constraint

In practice, sintering often occurs under some sort of constraint. Unless the sintering is done under vacuum, gases will be trapped in the isolated pores and will resist densification; that problem was analyzed by Mackenzie and Shuttleworth (1949). Another sort of internal constraint arises when the body contains a distribution of pore sizes or particle sizes; then, as indicated by Eq. (5), the sintering rate varies from place to place within the body. Regions that tend to contract more rapidly (i.e., locations where S is large) are subjected to restraint (tensile stress) by the surrounding regions that contract more slowly. A similar situation results when there is a gradient in composition that creates a spatial variation in viscosity. This was found to be a significant issue in the sintering of preforms for optical waveguides (Scherer, 1979), where a composition gradient is deliberately created to produce total internal reflection within the fiber; that gradient also causes a strong spatial variation in sintering rate, affecting the course of densification. In a composite, there may be filler particles or fibers that impede the contraction of the porous glassy matrix in which they are embedded. In addition to these internal constraints, there may be external constraints, as when a sintering film is attached to a rigid substrate, or when a mechanical load is applied during sintering (a process called *hot pressing*).

Constitutive Equation

To analyze constrained sintering, it is necessary to generalize Frenkel's energy balance, by adding a term for the mechanical work done by the stresses. The result is a constitutive equation for a sintering material with the following form (Scherer, 1979):

$$\dot{\epsilon}_x = \dot{\epsilon}_f + \frac{1}{F} (\sigma_x - N(\sigma_y + \sigma_z)) \quad (7)$$

where $\dot{\epsilon}_x$ is the strain rate in the x direction and σ_x , σ_y , σ_z are the applied stresses in the x , y , and z directions. The free strain rate,

$\dot{\epsilon}_f$, is the linear contraction rate of the sintering body in the absence of applied stresses; since the linear contraction rate is $1/3$ of the volumetric contraction rate,

$$\dot{\epsilon}_f = \frac{1}{3} \frac{dV}{V dt} = - \frac{1}{3} \frac{d\rho}{\rho dt} \quad (8)$$

The negative sign reflects the fact that the body contracts as its density increases. Using Eq. (5), the free strain rate can be written as

$$\dot{\epsilon}_f = - \frac{\gamma S \rho_s}{6 \eta} \quad (9)$$

The quantity $F(\rho)$ in Eq. (7) is the uniaxial viscosity for the porous viscous material, which is a measure of the additional strain rate resulting from the applied stress. For example, if the material is subjected to a uniaxial stress σ_x , that stress causes the strain rate in the x direction to change by σ_x/F , so that the total strain rate in that direction is

$$\dot{\epsilon}_x = \dot{\epsilon}_f + \frac{\sigma_x}{F} \quad (10)$$

If the stress is compressive ($\sigma_x < 0$), then the contraction rate increases (becomes more negative), whereas tensile stress opposes the free strain rate and retards the contraction. For a nonporous liquid, $F(1) = 3\eta$, but for a porous body $F(\rho) < 3\eta$. The quantity

$N(\rho)$ in Eq. (7) is Poisson's ratio for the porous body; for a nonporous liquid, $N(1) = 1/2$, but for a porous body $N(\rho) < 1/2$. A variety of functional forms that have been proposed for F and N are reviewed by Bordia and Scherer (1988) and Olevsky (1998). Most of those models predict that F increases roughly as ρ^2 ; however, the actual dependence depends strongly on the microstructure. For example, if particles are packed into a random dense arrangement, with $\rho \approx 0.63$, the viscosity F may be very small, because the particles initially make point contacts with one another. As sintering causes the contact area to increase (as illustrated in Fig. 1), the resistance to deformation increases and F rises rapidly. This effect is captured in the simulations by Jagota and Dawson (1988), who found that F was approximately proportional to the square root of the contact area between sintering spheres during the initial stage of sintering.

Practical Applications

Given an expression, such as Eq. (9), for the free strain rate and theoretical or experimental expressions for $F(\rho)$ and $N(\rho)$, it is possible to use Eq. (7) to analyze sintering in the presence of internal constraints (such as non-densifying inclusions, or gradients in density, viscosity, or pore size) or external constraints (such as applied loads or attachment of a sintering layer to a substrate). Thorough reviews of the literature on constitutive equations and numerical analyses of problems in constrained sintering are given by Olevsky (1998) and Bordia *et al.* (2017). Analytical solutions can be obtained for the rate of densification in some cases of practical importance (Scherer, 1992). For a film on a rigid substrate, the rate is

$$\frac{1}{\rho} \frac{d\rho}{dt} = - \left(\frac{1+N}{1-N} \right) \dot{\epsilon}_f \quad (11)$$

Comparison with Eq. (8) reveals that the film sinters more slowly than a free body, as long as $(1+N)/(1-N) < 3$, which is the case whenever $\rho < 1$. By inhibiting its contraction, the substrate imposes tensile stress within the sintering layer. Bordia and Jagota (1993) showed that cracking of the film can occur when the layer thickness exceeds a critical value.

For a porous body containing a small volume fraction v of rigid (i.e., non-sintering) inclusions, the viscous sintering rate is

$$\frac{1}{\rho} \frac{d\rho}{dt} = (3(1-v)\dot{\epsilon}_f) / \left(1 + \frac{2(1-2N)}{1+N} v \right) \quad (12)$$

Eq. (12) is valid only if the inclusions do not interact, which means that v must be less than ~ 0.1 . At higher volume fractions, the inclusions are likely to form a percolating network, so the densification rate is much more strongly retarded than is predicted by Eq. (12). If a noncrystalline material begins to crystallize while it is sintering, the crystals constitute rigid inclusions. If the fraction crystallized is small, then the effect can be described by Eq. (12), but if the crystallites form a continuous network, then sintering is drastically slowed (Brinker and Scherer, 1990).

In hot pressing, the applied load is usually so large that the effect of surface tension on viscous flow is negligible. The MS model then reduces to

$$\frac{\ln[1-\rho[t]]}{\ln[1-\rho[0]]} = \frac{3 p t}{4 \eta} \quad (13)$$

where p is the applied pressure. Eq. (13) indicates that an infinite amount of time is required to reach full density, $\rho = 1$, whereas full density is reached in a finite time when no pressure is applied. The discrepancy results from the fact that the capillary pressure in a pore with radius r is equal to $2\gamma/r$, so it becomes infinite as the pore collapses; therefore, the capillary pressure cannot be neglected with respect to the applied pressure at the end of sintering. That is, Eq. (13) only applies while the pores are large enough to justify the assumption that $p \gg 2\gamma/r$. Nevertheless, applied pressure can drastically reduce the time required to sinter a body, particularly if the pores are initially large.

Future Directions

Compared to crystalline materials, the sintering behavior of noncrystalline materials is quite simple: the rate is relatively insensitive to the details of the microstructure, so the time needed to reach full density can be estimated with reasonable accuracy given only the viscosity and the mean pore size. To predict in detail the evolution of the density and pore size distribution with time, it is necessary to know the initial state of the sample (distribution of pore size, density, and viscosity); however, such calculations are possible with the existing theory. The most challenging problem remaining in the field of viscous sintering is to develop appropriate constitutive equations for the analysis of constrained sintering. The difficulty is that the functions F and N are sensitive to the microstructure (particle shape, contact area, connectivity of voids, and so on). Moreover, the properties may be anisotropic as a result of processing of the unfired body (such as pressing of powder compacts), or may be isotropic at the start of sintering, then become anisotropic as a result of the constraint (e.g., during uniaxial pressing). Considerable progress is being made in this area through careful experimental work and detailed numerical simulations. Much of this work is described in the review by Bordia *et al.* (2017).

Hot Pressing and Hot Isostatic Pressing

Mathias Herrmann and Jan Rätzel, Fraunhofer Institute for Ceramic Technologies and Systems, Dresden, Germany

© 2021 Elsevier Inc. All rights reserved.

In addition to Gas Pressure Sintering, Field-Assisted Sintering Technology/Spark Plasma Sintering (FAST/SPS) and High-Pressure, High Temperature (HP/HT) methods (production of polycrystalline diamond) Hot Pressing (HP) and Hot Isostatic Pressing (HIP) are pressure-assisted sintering methods. They allow.

- (1) To densify materials that are difficult to sinter,
- (2) To significantly reduce the sintering temperatures, which makes it possible to produce particularly fine-grained or thermally unstable materials,
- (3) To produce materials with increased reliability and strength, since the additional external pressure increases the driving force of the compaction and thus the number of defects (pores, microcracks, etc.) can be decreased.

Both methods are fundamentally different. In hot pressing, a powder or a compacted preform is densified by simultaneous application of a uniaxial pressure and temperature (Fig. 1). On the other hand, in hot isostatic pressing, pre-sintered, gas-tight components or components encapsulated into gas-tight metallic or glass containers are exposed to an isostatic gas pressure and temperature, which allows the compaction of complex-shaped components (Fig. 2). While in the hard metal industry, for example, the term HIP is used for sintering with gas pressures of 50–100 atm (5–10 MPa), in the ceramic industry the term gas pressure sintering is attributed for processes with these pressures. HIP of ceramic materials usually requires 1000–2000 atm (100–200 MPa).

Hot Pressing

Technology

Hot presses typically consist of two counter-moving punches and a die, which enclose the pre-compacted powder, integrated in a furnace (induction or resistance). This allows pressure and temperature to be applied simultaneously. Often the systems allow the atmosphere to be controlled by appropriate furnace design. Also, the hot pressing systems are very similar to FAST/SPS-systems with the main differences that in the hot press the heat is generated outside the sample whereas in FAST/SPS a direct current is passing through the material, punches and dies. Therefore, the heating rates applied are usually much lower than for the FAST/SPS processes (Guillon *et al.*, 2014).

Graphite is typically used as punch and die material which can be used up to 2500°C. It possesses the following advantages: low cost, easy machinability, superior thermal shock and creep resistance up to high temperatures and acceptable bending and compressive strength values. The low coefficient of thermal expansion compared to those of most other suitable tool materials enables the ejection of the sample, as the die does not shrink onto the material. Due to the average strength values of the graphite,

Fig. 1 Figure of a typical hot press allowing to densify several samples at once and schematic view of the internal part of the hot press. Reproduced from "FCT Systeme GmbH, 2020". Available at: <http://www.fct-systeme.de/Vakuumheisspressen>.

Fig. 2 Hot isostatic press operating in the IKTS Dresden with maximum usable volume of 300 mm diameter and 400 mm height and schematic view of the furnace.

the typical applied pressures are limited in the range 10–30 MPa for larger sized tools. The use of Carbon Fiber Composites (CFC) dies or CFC covers sleeves on graphite dies increasing safety and maximum applicable pressure.

The high reactivity of graphite with ceramic systems is sometimes critical. To limit this problem, hexagonal Boron Nitride (hBN) coatings established on tool parts are of particular interest. For special applications (e.g., lower temperatures or higher pressures, sensitivity of the material to graphite) other materials or at least “inliners” such as W, Mo-alloys BN, Al_2O_3 , SiC, TiB_2 , TiC, hard metals, WC and other could be applied.

Since the powder is situated in a dense press mold, it is relatively well shielded from the atmosphere. This means that the atmosphere inside the press mold can significantly differ from the furnace atmosphere. Therefore, it is possible to sinter Si_3N_4 -ceramics without inert gas in an inductive hot press without oxidation of the material. Such relatively simply constructed hot presses without a controlled adjustable atmosphere have not become established for non-oxide materials, as their operation showed no good enough reproducibility.

The main disadvantages of hot pressing are its limitation to relatively simple geometries, typically plates and cylinders, the difficultness to full automation and comparatively high operation costs. There are attempts described in literature to quasi-isostatically sinter parts, encapsulated into a non-sintering powder as pressure transmitting medium, but this is so far of academic interest only (German, 1996).

In addition, the use of the process is limited by the relatively low productivity, since usually only single components are produced. Special techniques such as tandem systems, rapid cooling, simultaneous pressing of several components (Fig. 1), approaches to (partially) automatize the process etc. are applied to increase productivity. An example of such a system which can produce up to 40,000 panel-shaped parts per year is shown in Fig. 3.

Therefore, hot pressing is limited to materials that cannot be compacted in another technology in an effective way (e.g., BN based ceramics, SiC-whisker-reinforced Al_2O_3 ceramics, B_4C materials, scintillator materials, etc.), or where small quantities and/or the highest demands on density and purity with relatively simple geometries are required, e.g., sputter targets. However, complicated multi-layer plate heaters with electrically conductive and insulating areas can be produced by hot pressing too (“Bach Resistor Ceramics GmbH, 2020”).

Today, hot pressing systems up to 700 mm diameter and 2500 °C are available on the market (“FCT Systeme GmbH, 2020”; “FCT Anlagenbau GmbH, 2020”).

In addition to industrial applications hot presses are used in academic field to test the potential of new materials, since sophisticated processing and shaping to avoid defects is not necessary and testing samples can be fast and easily produced by this technology. Hot pressing is a primary forming technology. Within the last three decades, FAST/SPS systems have been increasingly used for these purposes, which offer quick heating and therefore, a much faster production of samples (Guillon *et al.*, 2014; Nygren and Shen, 2012).

Densification Mechanisms During Hot Pressing

The application of a uniaxial pressure represents a significant additional driving force, which enforces the sintering in various ways:

Fig. 3 Continuous–Hot pressing system with preheating channel, double pressing station and cooling channel (rapid cooling). Reproduced from “FCT Systeme GmH, 2020”. Available at: <http://www.fct-systeme.de/Vakuumheisspressen>.

- (1) The permanently acting force increases strongly the particle rearrangement in the initial phase of sintering. This is especially true when, due to the formation of a liquid phase or due to impurities on the surface, lubricating films are formed which allow grains to slide easily against each other. Especially in systems with anisotropic grains (e.g., Si_3N_4 -ceramics) this leads to the formation of textures due to the alignment of the grains.
- (2) Grain boundary sliding and diffusion creep are enhanced. In many solid phase sintered materials, this mechanism becomes the dominant one in the intermediate and final stage of sintering.
- (3) Especially in the final stage of sintering, mass transport is favored by increasing gradients of chemical potential or dislocations.

The rearrangement intensified by the external pressure (initial stage of sintering) is rather difficult to describe analytically and it strongly depends on the pre-compaction, the grain shape, size, and the formation of viscous phases.

The compaction in the main phases of the densification (Phase II and III) can be described with different equations depending on the mechanism (Rahaman, 2008; Kang, 2008):

Provided that the applied pressure P_a is much higher as the sintering stress (this is usually the case), for solid phase and viscous sintering the densification rate can be described by

$$\frac{d(\rho)}{\rho dt} = \left(\frac{HD}{G^m kT} \right) (P_a \phi)^n \quad (1)$$

where ρ is the relative density, H is a constant, k the Boltzmann constant, T the temperature, D is the diffusion coefficient of the relevant diffusion mechanism (grain boundary; lattice diffusion) G is the grain size P_a is the applied pressure and ϕ is a stress intensification factor that reflects the stress amplification at pores,

The exponent m and n depend on the densification mechanism. m can be between 0 for viscous flow and 3 for grain boundary diffusion. The values of n could be $n = 1$ (grain boundary or lattice diffusion), $n = 1 \dots 2$ for grain boundary sliding, particle rearrangement and $n > 3$ for viscous flow.

Different functions are proposed for the dependence of ϕ on the density (German, 1996). A common one is

$$\phi = e^{aV_p} \quad (2)$$

where a is a constant and V_p is the porosity. It approaches 1 when the porosity is 0 and can exceed 10–50 for compacts with 60% theoretical density. This means, that the influence of the applied pressure is higher for less dense materials and corresponds to the applied pressure for dense materials.

Using Eq. (1), the value of the exponent n and thus the densification mechanism can be determined by evaluating the dependence of the densification rate on the applied pressure at constant density. In most solid-phase sintered ceramic materials, this value is approximately 1, which suggests a diffusion mechanism as the speed-determining mechanism. However, often the results are inconclusive and additional investigation or modeling of the compaction with separately determined constants is necessary to unambiguously determine the mechanism. Especially for the model system of high-purity Al_2O_3 ceramics, the dependence of the densification mechanisms on the grain size and the densification temperature are determined in detail (Rahaman, 2008; Kang, 2008).

In the case of liquid- phase sintering the following equation can be applied (German, 1996):

$$\frac{d(\rho)}{dt} = \frac{3\phi P_a V_p}{4\eta} \quad (3)$$

Where ρ is the relative density and V_p is the porosity ($V_p = 1 - \rho$), P_a is the applied pressure, and ϕ is a stress intensification factor that reflects the stress amplification at pores.

The viscosity is the apparent viscosity depending on the viscosity of the liquid and the volume fraction of the solid:

$$\eta = \frac{\eta_0 \exp(-aV_p)}{(1-c\phi^*)^2} \quad (4)$$

where a and c are empirical constants that are typically between 1 and 2, and ϕ^* the relative volume fraction of solid. The inherent viscosity of the liquid phase (η_0) depends on the temperature and composition.

Rahaman (2008) describes an alternative approach:

$$\frac{d(\rho)}{pdt} = \frac{AD_l\delta_l\Omega}{G^3kT} P_a\phi \quad (5)$$

where A is a constant depending on geometry, δ_l is the thickness of the liquid layer around the grains, D_l is the diffusion coefficient in the liquid and Ω is the atomic volume of the rate controlling species. Since the diffusion coefficients are indirectly proportional to viscosity, the Eqs. (3) and (5) result in a similar dependence on viscosity. The thickness of the films of the liquid phase δ_l (equation) is a measure of the volume fraction of the liquid phase. Therefore, if other parameters are constant, the densification rate should be proportional to the volume of the liquid phase. However, it must be taken into consideration that grain growth is also dependent on the amount of liquid phase, so, the dependencies are often only qualitative in accordance with the prediction. The maximal useful amount of liquid phase is limited to <10–20 vol% due to the fact, that excess of liquid phase will be quizzed out in the final densification step. This strongly depends on the applied load, the wetting behavior and the viscosity of the liquid.

The modeling of processes often based on parameters obtained from experimental compaction curves and some fitting parameters. A detailed description of the modeling of hot pressing and very similar FAST/SPS processes are summarized in (Guillon *et al.*, 2014; Bordia *et al.*, 2017; Olevsky *et al.*, 2012; Guyot *et al.*, 2014).

Models predict that with shear stresses the densification could be additionally improved. Therefore, different setups for sinter forging or hot extrusion were explored, showing the possibilities of these methods especially for fine grained materials. However, up to now they have not found its industrial application.

The recently developed cold sintering process is a special kind of a reactive hot pressing. The powder is mixed with small amount of water and additional substances to control the dissolution reaction under hydrothermal conditions. The densification of ceramic components takes place at relatively low temperatures $\leq 400^\circ\text{C}$ at 100–300 MPa pressure under hydrothermal conditions. The solvent enhanced recrystallization under pressure is the mechanism of this kind of densification. The slow escape of water and additional substances has to be controlled by a special die design. Detailed information about this new hot topic could be found elsewhere (Grasso *et al.*, 2020; Vakifahmetoglu and Karacasulu, 2020).

Hot Isostatic Pressing (HIP)

Hot isostatic pressing (HIP) is a sintering process used for the consolidation of both metallic and ceramic components receiving parts with the highest reliability and lowest scattering of properties. The principle of HIP technology is that a shaped body, gas-tight (in rare cases a powder in a gas-tight mold) which is simultaneously exposed to high gas pressure and high temperatures up to 2000°C . In order to generate an isostatic pressure on the component, the component itself must be gas-tight or gas-tight encapsulated (see below). The commonly used pressure range is 70–400 MPa, which is higher than the 10–30 MPa used for typical hot pressing or gas pressure sintering (up to 20 MPa). As a result of the high isostatic pressure, non-porous components with greatly reduced scattering of mechanical properties in particular can be produced. Therefore, the process is used especially for products requiring highest reliability, e.g., ceramic hip implants, ball bearings or demanding ceramic wear parts. However it is also used to remove inner defects like shrink holes of metallic alloys, like Ti-alloys (aircraft components, medical devices), Al-alloys, Ni-base super alloys (jet engine turbine blades...), 17–4PH stainless steel and others ("Kobelco Kobe Steel Group 2020"; Bocanegra-Bernal, 2004; Atkinson and Davies, 2000; European Powder Metallurgy Association, 2018).

In addition, sintering temperatures can often be lowered compared to a pressureless sintering process, which reduces grain growth, in some cases eliminates or at least reduces the need for sintering additives and growth inhibitors. In addition to the production of such highly stressed ceramic components, HIP-technology is also used for transparent and optically active ceramics, such as MgAl_2O_4 , cubic- ZrO_2 or rare earth compounds with a cubic structure (e.g., garnet). In these materials, the porosity can be reduced to values below 0.001% by isostatic pressure. This is necessary because the pores act as scattering centers. The effect of the HIP process on the transparency of MgAl_2O_4 ceramics is shown in Fig. 4.

Additionally, the importance of the HIP-technology is currently increasing in connection with the additive manufacturing of metallic components, since components made of titanium and other superalloys, which are produced in this way, are hot isostatically post-compacted to reduce porosity and to achieve the corresponding properties and reliability. In most cases, it is worth to print parts at higher speed with low accuracy and Post-HIP those parts to fully density them.

In addition to sintering of components, HIP can be used for diffusion bonding (diffusing bonding of nuclear fuel elements was a starting point of the development in the 1960th in the US) as well as for cladding and reactive HIP processes or syntheses (Bocanegra-Bernal, 2004).

Fig. 4 Photo of a spinel plate before and after HIP process (a). Figure (b) shows the micrograph after HIP showing the elimination of the porosity.

Unfortunately, HIP processes cannot completely eliminate all defects (see Mechanisms), therefore the process does not replace sophisticated processing especially in ceramic technology.

A HIP- system and its schematic operation is shown in [Fig. 2](#).

Two types of pressure vessel are used today, on the one hand a pre-stressed and wire-wound with high tensile cold-rolled spring steel ribbon (Quintus Technologies, Sweden), or on the other hand, forged vessels, massive, monolithic pieces of forged steel (EPSI Belgium, Cremer HIP Innovations GmbH, Germany). The York frame is typically made of steel or wire-wound ensuring a calculated fatigue life of more than 20,000 cycles. Two main types of heaters are in operation, metallic heaters (steel or molybdenum) for medium temperature applications up to 1350°C or graphite and/or Carbon Fiber composite (CFC) heater installation for temperatures of up to 2200°C reported in literature. Argon as pressure transmitting media is commonly used, but also nitrogen and in few cases air or hydrogen.

They are available for a wide range of dimensions (diameters from some centimetres up to more than a meter) and temperatures ([EPSI Hot Isostatic Presses, 2020](#)). Due to the high gas pressure, special safety systems and special thermal insulation are necessary, as the gases have a high density (Ar has a density $> 1 \text{ g/cm}^3$ at room temperature and 100 MPa) and low viscosity. In addition, appropriate monitoring and control systems and peripheral safety equipment ensure safe operation. The majority of used in the ceramic production HIP systems work with nitrogen or argon and use graphite or CFC-heaters up to 2000°C. There are only a few systems that can operate under oxidizing conditions $> 1000\text{--}1200^\circ\text{C}$. These typically have Pt/Rh heaters. For metals that are compressed at lower temperatures and where carburization must be avoided, metallic heaters, Nichrome, Kanthal or even Mo- or W-heater for higher temperatures are used.

The use of carbon or Carbon Fiber Composite (CFC) heaters for Post-HIP consolidation of oxide ceramic materials (Al_2O_3 ; ZrO_2 ; ATZ, spinel...) can lead to oxygen vacancies in the ceramic, which can cause a gray coloring. In order to minimize these effects, the samples are shielded by crucible materials or even powder beds. If necessary, discoloration can often be achieved by subsequent oxidizing annealing.

The additional driving force by the external pressure requires that the porous ceramic preform is separated from the gas by a gas-tight casing. This can be done in various ways. Three main routes are used:

- (1) Sinter-HIP process.
- (2) Encapsulation method.
- (3) Glass bath method.

These processes are shown schematically in [Fig. 5](#).

The route mainly used in ceramics production today is the Post-HIP or Sinter-HIP-process [Fig. 5\(a\)](#): Ceramic or powder metallurgical produced metallic green bodies have essentially open porosity, i.e., the pores have a connection to the surface. The gas pressure in these pores corresponds to the gas pressure in the environment. Therefore, no pressure gradient can occur with increasing gas pressure during HIP. Open porosity is typically the dominant one up to sinter densities of 90%–95% theoretical density. At higher densities, the sintered bodies have closed porosity, which have no connection to the surface of the component ([Fig. 6](#)). Only in this stage of sintering a pressure difference arises between the body and the surrounding gas when the gas pressure is increased, which facilitates the sintering. This means that the component has to be pre-sintered to a density of $> 90\%\text{--}95\%$ of

Fig. 5 Schematic view of the different HIP-technologies.

Fig. 6 Schematic view of the cross section of the component before and after Post-HIP. Open pores and cracks with a connection to the surface could not be healed out. Empty closed pores or filled with a gas, which diffuse along grain boundaries or solve in the matrix, could disappear completely. Pores filled with Argon (Ar) or another non-diffusing gas could shrink, but will not completely disappear. Large pores could be filled in liquid phase sintered materials during post HIP with the liquid component. It will then solidify during cooling (see also Fig. 7).

theoretical density at a low gas pressure (1 atm) or in vacuum and only then the high gas pressure has to be applied to accelerate the final densification. The pre-sintering can be done in the HIP or in an external unit. The latter increases the flexibility of the usable atmospheres. For this reason, separate pre-sintering and post-HIP-ing are usually used, especially for oxide ceramic components.

The influence of the gas pressure on the densification rate during post-compaction can be described as follows for grain boundary, volume diffusion - diffusional flow (German, 1996; Atkinson and Davies, 2000):

$$\frac{d(\rho)}{dt} = (1 - \rho)B \left(g \frac{\gamma_{sv}}{r} + P_{ae} - P_p \right) \quad (6)$$

where γ is the surface energy, r is the pore radius and g is a term determined by the geometry, P_{ae} is the effective external gas pressure and P_p is the gas pressure in the pores. For densification by plastic flow or creep, the densification rate is a power function of pressure (Kang, 2008; European Powder Metallurgy Association, 2018). A corresponding detailed discussion of the mechanisms

Fig. 7 Microstructure of Si_3N_4 material in the sintered state showing some defects from the processing and in the hipped state. In the HIP-ed state the pores are filled with the Y_2O_3 rich glassy phase.

can be found in (Kang, 2008; Bocanegra-Bernal, 2004; Atkinson and Davies, 2000), whereby for solid-phase sintering ceramics under typical conditions the diffusion processes are the dominant ones.

From equation (Fig. 6) it can be deduced that if non-diffusing gas is trapped in the pores the pores cannot be removed completely. An equilibrium pore size is reached when the expression in brackets becomes 0. Based on this the equilibrium pore size can be calculated:

$$\frac{P_{in}}{P_a} = \left(1 + \frac{2\gamma}{P_a r_{eq}} \right) \left(\frac{r_{eq}}{r_{in}} \right)^3 \quad (7)$$

where r_{in} and P_{in} are the initial radius of the pores and pressure at the moment of pore closure respectively, r_{eq} and P_a are the equilibrium radius and the external gas pressure during the sinter-HIP stage (Herrmann *et al.*, 1992; Kang *et al.*, 1989).

Therefore, pre-sintering should be carried out at the lowest possible gas pressure, or the gas used should exhibit as fast diffusion along the grain boundaries or in the liquid phase. The conditions for the gas to be used in the pressure stage is, that it has only a low solubility in the solid, otherwise the pores can be stabilized by the inward diffusion of the gas. This could result also in swelling in post HIP heat treatments (Kwon and Messing, 1989).

For liquid phase sintering systems, large pores can also be healed by filling with liquid phase. Due to the external pressure, it is possible that not only small pores are filled with the liquid phase due to capillary forces, but also large ones. Fig. 6 shows this for a Si_3N_4 ceramic. However, these larger glass pockets are similarly critical for Si_3N_4 bearing balls (ISO, 2017). This is one example showing the limitations of the HIP sintering. It cannot heal all defects during shaping. Therefore, high quality materials do not only require pressure assisted methods, but also sophisticated processing. The healing of pores in the final stage is mostly done by diffusion processes, therefore larger pores need longer sintering times for complete healing, which can significantly affect the microstructure. Which defects could be healed out is shown schematically in Fig. 6.

For metallic components not only Post-HIP processes are carried out. A combination of Post-HIP and subsequent annealing, solution treatment or aging can be performed as part of one HIP cycle. For that HIP devices can be equipped with a fan or channel blower and nozzles to increase the convection of compressed gas which allows fast cooling (up to 200K/min for small parts).

If pre-sintering up to densities > 90%–95% theoretical density is not possible, then gas tightness must be achieved with the aid of a capsule (Fig. 5(b)). The basic requirements for the capsule are ("Kobelco Kobe Steel Group 2020"; Bocanegra-Bernal, 2004; Atkinson and Davies, 2000):

- (1) Gas tightness at room and high temperatures but plastic deformability under the temperature and pressure conditions used to transfer the external pressure.
- (2) Compatibility with the encapsulated component to avoid reactions that can lead to leakage of the capsule or to diffusion zones in the material. Sometime it can be avoided by using intermediate coatings.
- (3) Low cost of capsule material and encapsulation and
- (4) Easy removability.

In the case of metals, the components or directly the starting powder are filled in the capsule (steel, super alloys Ta, Mo, W) and usually welded in vacuum. It should be noted that the edges of the capsules are deformed differently during the HIP process and therefore the pressure is not applied completely isostatic, which can lead to deviations in the shape of the component ("Kobelco Kobe Steel Group, 2020"; Bocanegra-Bernal, 2004; Atkinson and Davies, 2000; European Powder Metallurgy Association, 2018).

Additive manufacturing also enables the printing of complex-shaped parts combined with the printing of a gas-tight can. It thus opens up new possibilities for an effective capsule HIP process (Riehm *et al.*, 2019). In the future, it may also open up new possibilities for capsule technology for glass capsules, which are used in ceramic production. Until now, attempts have been made to create such capsules by immersion or spraying, but this has not been widely established.

Glass ampoules are often used for ceramics. In this process the workpiece is typically embedded in boron nitride powder by cold isostatic pressing before it is encapsulated in a quartz glass tube under vacuum. In this case the boron nitride powder acts as a pressure transmitter and avoids stress and reaction zones. This technology is the only one that has enabled the densification of Si_3N_4 materials without additional sintering additives (1800–1900°C; 1–2 GPa Ar pressure). Only the low amount of SiO_2 on the surface of the powder was sufficient for the densification.

To simplify the process of encapsulation, the glass bath method was invented (Fig. 5(c)), e.g., for Si_3N_4 ball bearing balls, this modified capsule technology is used. The balls are embedded in a fritted glass powder in a crucible and then the mixture is heated in a vacuum until the glass melts and the balls are embedded in the melt. The viscous glass is then used as a transmitter of the pressure. After the HIP-process it will be mechanically removed. High quality balls even with low sintering additives can be produced by this method.

All capsule methods have the disadvantage that they involve additional process steps of encapsulation and decapsulation, so that capsule-free Sinter-HIP methods are increasingly preferred.

Besides these mainly used methods of compression by means of HIP there is a whole range of process variants, such as high pressure reaction sintering methods, liquid-HIP methods (the latter uses liquid salts as pressure medium), which are tailored to special requirements (German, 1996; Atkinson and Davies, 2000).

Irrespective of the HIP process selected, materials with extremely high density can be produced which have both special optical properties (transparent ceramics), improved wear behavior increased strength and reliability (e.g., Al_2O_3 -hip implants, Ti alloys for aircraft components, Ni base alloys for power plant components). In addition, the absence of defects reduces the fatigue behavior of metallic alloys (e.g., Ti alloys) and ceramics. For example, it could be shown that the healing of small defects by a post HIP treatment in Y-stabilized ZrO_2 (TZP-ceramics) suppresses low temperature aging.

In addition to these improvements in the properties of conventional materials, it enables the production of materials or microstructures that could not be manufactured without the high pressure.

Reaction Sintering

Carmen Baudín, Instituto de Cerámica y Vidrio, CSIC, Madrid, Spain

Introduction

The Concept

The term sintering is used to describe the phenomena that occur when solid products are made from inorganic powder compacts. It is an important step in the fabrication of ceramics, metals, and cermets. During the sintering process, a powder compact is heated to a suitable temperature at which the mass transport mechanisms are operative. As a result of the initial misfit of the particles, the porous compact shrinks as much as the void volume is eliminated.

The sintering driving force is the decrease in the total free energy of the body leading to a minimal energy state. When the constituents of the particles in the porous compacts are solid state compatible and the thermal treatment temperatures are lower than those necessary to form liquid phases, the decrease in the total free energy of the body occurs due to the reduction of the overall interfacial free energy (solid-solid and solid-vapor). This process is referred as *solid state sintering*.

Reaction sintering (reactive sintering) is an alternative sintering process in which chemical reaction between the constituents of the green compact and its densification occur during the same thermal treatment.

Shrinkage of the compact is one main point in reaction sintering, therefore, it is different from processes in which only slight dimensional changes occur during densification and involve relatively low temperatures such as reaction bonding of non-oxides (e.g., Si_3N_4 , RBSN; B_4C , RBBC; SiC bonded with Si_3N_4) or oxides (Al_2O_3 , RBAO) or the directed metal oxidation (DMO) processes used for processing ceramic matrix composites (CMCs) with a continuous interconnected three-dimensional network of ceramic phase (Travitzky *et al.*, 2018; Nesmelov and Perevislov, 2015). These processes have high potential for near to net shape fabrication of parts. Even though they are sometimes included in the term reaction sintering, they will not be discussed in this chapter.

Since the energy changes for chemical reactions are much larger than those for surface area changes it would be very desirable if the free energy of the reaction could be used to drive the densification process (Rahaman, 2008). However, there is no evidence that the energy of the reaction can act directly as a driving force for densification. Major advantage of reaction sintering is the elimination of additional thermal and milling treatments needed to fabricate powders with the characteristics required in the final material. Therefore, it appears as an attractive industrial process for cost-saving (Brook, 1991).

Technological Interest

Reaction sintering has long been successfully used in the case of the so called *traditional ceramics*. Building ceramics – bricks, roof and floor tiles-, crockery, and sanitary products are fabricated from mixtures of minerals, being phyllosilicates, feldspar, carbonates, and quartz the most frequently used.

Different mixtures that include non-calcined raw materials and depend on the desired microstructure and properties are also used to process shaped refractories. For instance, fireclays, andalusite, or sillimanite minerals are used for alumina-silica and high alumina bricks, which experience reaction sintering during the thermal treatment. In general, the refractory industry does not use un-calcined carbonates as raw materials even though a careful control of composition, grain size distribution, and firing temperature allows achieving magnesia-calcium zirconate refractories with optimized microstructures (Obregón *et al.*, 2011).

Reaction sintering is also a fundamental process in monolithic refractories. Performance of these materials in which reactions occur during use is closely linked to the microstructural development at high temperatures. In this sense, the strict control of the development of high temperature calcium aluminate phases in those containing cements, or mullite in the no cement alumina castables and the shrinkage of the material is a main technological requirement.

For more information about traditional ceramics and refractories, readers are directed to comprehensive books and/or handbooks such as Boch and Niepce (2007), Heimann (2010), and Schacht (2004).

Highly-performing ceramic materials with specific mechanical, electrical, thermal, and/or biochemical properties are usually referred as *technical ceramics* (or *advanced ceramics*). Most developments on technical ceramics have been taken place since the last quarter of the last century. There are many books and handbooks dedicated to technical ceramics. Also they are usually addressed in generalist books of ceramics (e.g., Boch and Niepce, 2007; Heimann, 2010).

In the production of technical ceramics, it is usual to have synthetic powders as raw materials because, in general, their use helps achieving final products with superior final properties. As it will be discussed in which follows, reaction sintering of compacts made of synthetic powders has been developed for the fabrication of electronic as well as structural ceramics. Also, reaction sintering of milled powders of natural raw materials with controlled amount and nature of impurities has been demonstrated as an adequate method for the fabrication of technical ceramics. Moreover, the necessity of solid waste control has opened a new opportunity for reaction sintering.

Fig. 1 Relative density (R.D.) vs. fraction of advance of reaction (α) for the different paths that reaction sintering can follow: I: First densification of the compact followed by reaction. II: Simultaneous densification and reaction. III: First reaction between the constituents of the compact followed by densification.

It has to be highlighted that the use of natural raw materials and reaction sintering allows obtaining materials based on compounds such as mullite, of high interest for traditional as well as technical ceramics, which are scarcely found in nature and their synthesis via solid state reactions require repeated milling processes and high temperatures.

Processes and Factors

As described above, there are two main points regarding this alternative sintering process: (1) two or more incompatible reactants are homogeneously mixed and subsequently heated to a suitable temperature where sintering and reaction take place; and (2) the possible appearance during heating of a liquid phase that enhances sintering and/or reaction at lower temperature. This liquid might disappear after the thermal treatment – transitory liquid – or remain in the material as glassy phase. In this later case, its distribution through the microstructure is determinant of the properties of the material. Many variants of liquid phase sintering are applied to a wide range of engineering materials, a complete updated review can be found in reference (German *et al.*, 2008). In reacting powder systems, reaction and densification can both occur, and it is useful to be able to control the rate at which each of those phenomena proceeds when fabricating the desired microstructures.

The potential trajectories that a reactive compact can follow at high temperature are plotted schematically in Fig. 1. Systems following path I are those in which densification occurs prior to reaction and in those following path III reaction occurs before densification starts. Path II combines reaction and densification during the thermal treatment. Apart from the composition of the starting mixture, the path followed by a reactive green compact depends on processing parameters such as particle size, temperature, heating rate, and applied pressure (Rahaman, 2008). When the objective is to prepare fully dense (i.e., zero porosity) fine grain materials, it would be preferable to complete porosity removal prior to the reaction (Path I). If reaction precedes porosity removal, the heat treatment necessary to eliminate the pores also would allow grain growth, making it difficult to retain the grains at the desired size. For the reaction to take place in dense materials without microstructure degradation, the difference between the molar volumes of the reactants and the product has to be small.

In principle, single as well as multiphase materials can be processed by reaction sintering. However, this process presents practical shortcomings that preclude its general use, in particular, for the fabrication of single-phase ceramics. Incomplete reaction might lead to compositional heterogeneities and the microstructural changes associated to the reaction would lead to reduced densification rates and difficult the microstructural control. Reaction sintering is better applied to the fabrication of composites, i.e., materials that require heterogeneity as a microstructural characteristic.

Reaction Sintering in the Presence of Transitory Liquids

A goal of great interest in advanced polycrystalline materials technology is the preparation of theoretically dense sintered compacts with specific microstructure. In this sense, reaction sintering was proposed as an inexpensive way to obtain advanced composite ceramic materials with controlled microstructures following quite conventional processing routes by using the concept of transitory liquid phase.

In such a case, during the reaction sintering process a liquid phase appears at a fixed temperature below the temperature of treatment. This liquid phase will enhance the rate of the reaction sintering because the driving force will be the one corresponding to a reaction sintering in the presence of a permanent liquid phase. Along the process the liquid composition will change up to its disappearance. In this way, it is possible to avoid a decrease in the mechanical properties of the final compact, produced by the presence of a liquid phase.

Fig. 2 Phase equilibrium diagram of a binary system, A-B, with two eutectic points at temperatures T_{e1} and T_{e2} and an intermediate compound, AB.

Reaction sintering by transient liquid phase can be easily understood taking into account a binary system, A-B, such as the one plotted in **Fig. 2**, in which a binary compound AB, compatible with A and B, is formed and which has two eutectic points at temperatures T_{e1} and T_{e2} . It is possible to prepare a sintered material of composition x starting from a homogeneous mixture of either A and AB or A and B. In the first case, to avoid the presence of a permanent liquid phase in the final compact, the starting powders must be heated at a temperature below T_{e1} . Reaction and densification will take place in solid state, thus, rates will be relatively slow even for those temperatures close to the eutectic point T_{e1} . When a mixture of A and B is used as starting powder, a local reaction takes place in the grain boundary between A and B during the first stages of the process giving AB as a product. Then, when the treatment temperature is higher than T_{e2} , the liquid phase corresponding to the invariant point of the system AB-B will appear at the grain boundaries AB-B. As the process proceeds, the binary compound and the transitory liquid form. This liquid increases the mass transport rate leading to an increase in the reaction and in the densification rates. At the end, the amounts of AB and A obtained in the presence of a transient liquid are the same as those in the case of a homogeneous mixture of A and AB. The advantages of the former method against the latter one are (1) the temperature necessary for the reaction sintering to take place is lower and (2) the kinetics of the process are higher due to the presence of the transitory liquid phase.

It is also possible to have the advantages of a transient liquid by using starting powders that will form a solid solution at equilibrium but will pass through a liquid stage before equilibrium is reached. Some other processes that can also lead to materials with good properties are liquid phase sintering followed by the crystallization of the liquid at the grain boundaries or working with systems in which the liquid remains isolated by the crystalline grains in the final material.

Reaction Sintered Technical Ceramics

In the field of advanced (or technical) ceramics reaction sintering was first proposed for structural ceramics and nowadays it has been proposed for a broader range of applications, especially for electronic ceramics (Loiu, 2015). Reaction sintering to fabricate single-phase or composite ceramics requires different technological approaches. In this section, the specificity of each approach is described. For composites, mullite-zirconia materials are discussed because reaction sintering in this system is one of the most studied and nowadays it can be considered as a model system to analyze the potential of this processing method.

Single-Phase

Reaction sintering to reach single-phase materials occurs via path III because reaction is relatively fast as compared to densification, thus, reaction is nearly finished before densification starts. Reaction sintering to form single-phase materials has been fully analyzed by Rahaman (2003, 2008). In this case, any change originated by the reaction in the microstructure of the compact plays a critical role. In those systems in which the molar volume of the mixture of reactants is similar to that of the product, reaction implies little volume changes and densification of the reacted compact occurs in the same way as that of a single phase compact. This is the case of zinc ferrite materials for which reaction sintering is an adequate production method. When the microstructure of the mixture compact is disrupted significantly by the reaction, reaction sintering cannot be applied for production. This is the case of the reaction of ZnO and Al_2O_3 to form ZnAl_2O_4 that implies large volume expansion (25–30 vol%) and the reaction product forms predominantly on a percolative network of the original Al_2O_3 particles that impede further densification.

The use of reaction sintering aids has been proposed in order to perform the reaction and densification simultaneously (Path II). The case of magnesium-aluminate spinel materials is a good example of such practice. “Spinelisation” reaction from its

Fig. 3 Characteristic microstructure of advanced mullite materials. (a) Scanning electron microscopy micrograph of a polished and thermally etched surface. (b) Transmission electron microscopy micrograph of an ion thinned specimen. From Baudín, C., 1997. Fracture mechanisms in a stoichiometric $3\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$ mullite. *Journal of Materials Science* 32, 2077–2086.

oxide precursors starts at 1000°C and continues beyond 1400°C and is accompanied by volume expansion, which hinders the densification of a reaction sintered spinel body in single step. In order to obtain full density and complete reaction, complex processing routes involving high temperature pressures (hot pressing or hot isostatic pressing) and two steps thermal treatments would be required. Therefore, enormous efforts have been concentrated to achieve the reaction sintering of spinel materials in a single treatment due to their technological interest. It has been proposed to use additives that would aid sintering by forming solid solutions (Sinhamahapatra *et al.*, 2018, 2019), or permanent or transitory liquids (Huang *et al.*, 1997). When the liquids are permanent their presence as intergranular phases might cause some degradation of the mechanical properties of the product, especially at high temperature.

Mullite-Zirconia Based Composites

Mullite ($\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$ to $2\text{Al}_2\text{O}_3\cdot \text{SiO}_2$) is a desirable phase to be present in ceramics because its low thermal expansion and thermal conductivity, creep resistance and high temperature stability (Schneider *et al.*, 2008). A reference book on mullite and mullite materials is Schneider and Komarneni (2005).

Main deficiency of mullite materials is their low toughness (e.g., Osendi and Baudín, 1996) which limits their use in responsibility applications. Improvement of the mechanical performance of mullite-based materials has been a goal of great technological interest during years. One classical means of enhancing the toughness of mullite is the dispersion of metastable tetragonal zirconia (ZrO_2) particles in the matrix that transform during fracture hindering crack propagation. Transformation toughening in mullite composites is also analyzed in the above mentioned book (Schneider and Komarneni, 2005).

Mullite is scarce in nature, only small amounts are found in the island of Mull, in Scotland, and its solid state synthesis requires high temperatures ($>1500^\circ\text{C}$) and repeated milling. Moreover, sintering of mullite-based materials requires relatively high thermal treatment temperatures ($\geq 1570^\circ\text{C}$). During the last quarter of the last century, reaction sintering was proposed and successfully applied for obtaining fully dense mullite-zirconia based composites.

The characteristic microstructure of advanced single phase mullite materials is shown in Fig. 3. It is formed by equidimensional mullite grains with small amounts of residual glass at triple points that comes from liquid formed during the heat treatment. The angles between this glass and the mullite grains (Fig. 3(b)) reveal that high temperature liquid wet mullite leading to an intergranular film of residual glass.

Reaction sintering of mullite-zirconia composites is done using zircon ($\text{ZrO}_2\cdot \text{SiO}_2$) and alumina (Al_2O_3) as starting materials. Initially, fabrication of mullite-zirconia composites using the stoichiometric proportions of the starting compounds given by Eq. (1) was proposed:

Different accounts of the reaction and densification sequence have been reported for this system. Powders with smaller sizes and higher level of impurities would densify first. In addition, the specific thermal treatment schedule can modify the kinetics of the process, as shown in classical works on this subject. For instance, Claussen and Jurgen (1980) used a two step thermal treatment in which densification of the compact occurred at 1450°C and a dispersion of fine zirconia particles in the mullite matrix was formed at temperatures above 1500°C (Path I Fig. 1). Di Rupo *et al.* found that reaction and densification were concurrent mechanisms (Path II, Fig. 1) in both, conventional sintering at temperatures between 1400 and 1600°C (Di Rupo *et al.*, 1979) and hot pressing at 1450°C (Gilbart *et al.*, 1979) and 1550°C (Di Rupo *et al.*, 1979).

Path III (Fig. 1) is not useful in this system because zirconia grain growth would take place during densification and the control of zirconia grain size is fundamental for the retention of zirconia in the metastable tetragonal phase needed for toughening to take place in the material.

The microstructure of the materials processed by two step sintering process was characterized by a close packing of fine faceted zirconia and fine mullite grains. When a single step thermal treatment in absence of pressure is used (Miranzo, 1985;

Fig. 4 Characteristic microstructure of reaction sintered mullite-zirconia composites sintered using a single thermal step (RSMZ). The major phase (gray) is the mullite matrix. Scanning electron microscopy micrograph of a polished and thermally etched surface. (a) Two kinds of zirconia particles (Z, white) and small alumina particles (A gray) embedded in mullite are observed. (b) Two kinds of zirconia particles, small alumina particles and partially reacted zircon grain (gray, arrow) are observed. Reproduced thanks to the kind permission of Miranzo, P., 1985. *Comportamiento mecánico de los materiales cerámicos tenaces multifásicos obtenidos por sinterización reactiva*. Universidad Autónoma de Madrid Spain (PhD Thesis).

Torrecillas *et al.*, 1993), the morphology of zirconia particles in the materials is different, as shown in Fig. 4. The microstructure of these materials is characterized by a close packing of equidimensional mullite grains and relatively large irregular shaped zirconia particles at the grain boundaries and some small rounded zirconia grains embedded in the mullite grains. Some non reacted zircon (Fig. 4(b)) and/or residual glassy phases are found in compacts because part of the mullite forms entrapping alumina grains (Fig. 4(a)).

In order to enhance reaction and densification in this system, the group of Instituto de Cerámica y Vidrio (CSIC, Spain) proposed the addition of small amounts of different oxides (e.g., CaO (Pena *et al.*, 1985), MgO (Miranzo *et al.*, 1985), and TiO₂ (Melo *et al.*, 1985)) to the mixtures as sintering aids. These aids allow nearly full reaction and densification of the materials at relatively low temperatures (1425–1450, 1450–1500, and 1450–1550°C, for CaO, MgO, and TiO₂, respectively) due to the formation of transitory liquids at temperatures lower than those of final treatment (<1400, ≤1425, and 1400°C, for CaO, MgO, and TiO₂, respectively). Small excess of alumina was added to the materials with CaO and MgO in order to form anortite (CaO·Al₂O₃·2SiO₂) or spinel (MgO·Al₂O₃) in the final materials.

Main problem of anortite is that it leads to degradation of the mechanical performance of the materials. The main advantage of TiO₂ is that it can enter in solid solution in mullite and ZrO₂.

In the case of MgO, Eq. (1) would be modified as:

In the presence of liquids, mullite grows as crosslinked tabular grains that form a tridimensional skeleton with zirconia particles embedded. In general, some residual glass is observed in regions of the microstructures isolated by the mullite skeleton. In materials with MgO, these regions are larger and more frequent when no alumina excess is added to form spinel (Orange *et al.*, 1985). Modifications of the initial compositions described by Eqs. (1) and (2) by adding significant amounts of extra alumina in the presence (Baudín *et al.*, 1986, 1987) or not (Torrecillas *et al.*, 1993) of MgO as sintering additive have been proposed as alternative means of reaching full reaction. The developed mullite-zirconia-alumina composites present much higher creep resistance due to the sharp reduction in the amount of harmful residual phases.

As described above (Fig. 4), most zirconia particles in reaction sintered mullite-zirconia materials without additives are relatively large (≥2 μm). These large grains transform into the stable monoclinic phase during cooling from the sintering temperature and, consequently, only small fractions of tetragonal zirconia are available for toughening of these materials (e.g., tetragonal zirconia fraction ≈0.2 Miranzo, 1985).

The microstructure originated by liquid phase sintering in mullite-zirconia-alumina materials fabricated with small additions of MgO (Fig. 5) is mostly formed by large mullite tabular grains with small (≤1 μm) intragranular zirconia round particles. There are also small areas with larger zirconia particles, alumina grains, some spinel particles, and residual glass, surrounded by the mullite matrix. The fraction of retained tetragonal zirconia in these materials is much higher (tetragonal zirconia fraction ≈0.6).

The reaction sintered mullite-zirconia and mullite-zirconia materials present a wide range of mechanical behaviors, determined by the specific microstructures. As an example, Fig. 6 plots results of thermal shock tests in water at room temperature for the three materials which microstructures are shown in Figs. 3–5. The composite material with equidimensional microstructure, small fraction of tetragonal zirconia and residual glass at grain boundaries presents just a slight improvement of the thermal shock behavior with respect to the single-phase mullite. On the contrary, the mullite-zirconia-alumina composite has higher strength, before and after thermal shock degradation and higher critical temperature interval.

Fig. 5 Characteristic microstructure of reaction sintered mullite-zirconia-alumina composites sintered using a single thermal step with MgO (MgO-RSMZA). Mullite (M) tabular grain with small alumina (A) and zirconia (Z) particles embedded (left) and larger alumina and zirconia particles at the boundaries (right) are observed. Scanning electron microscopy micrograph of a polished and chemically etched surface. (Baudín *et al.*, 1986, 1987).

Fig. 6 Results of thermal shock tests in water at 25°C for the materials of Fig. 3 (Mullite), Fig. 4 (RSMZ) and Fig. 5 (MgO-RSMZA). For Mullite and MgO-RSMZA, testing was done using bars of $3 \times 4 \times 50$ mm machined from the sintered blocks. Prior to testing, the bars were chamfered and the surfaces were rectified and polished (diamond 6 μm). Strength was measured in four points bending with 40–20 mm as outer and inner spans using 0.5 mm/min as loading rate. Data for the mullite-zirconia material come from the work by Torrecillas, R., Moya, J.S., De Aza, S., Gros, H., Fantozzi, G., 1993.

Zirconia transformation, together with the interaction of the crack with the specific microstructure – crack deflection and crack bowing, are responsible for this improvement.

Reaction Sintering Nowadays

Reaction sintering allows producing ceramic microstructures with unique properties. For instance, reaction sintering of alumina (Al_2O_3) and titania (TiO_2) to reach alumina-aluminum titanate ($\text{Al}_2\text{O}_3\text{-TiO}_2$) composites promotes the formation of aluminum titanate nanometric grains at the alumina grain boundaries. This microstructure is responsible for microcracking as the main toughening mechanism leading to a significant increment of fracture energy (Bueno *et al.*, 2008).

There is recent increased interest in reaction sintering due to the needs of alternative raw materials and of recycling waste from different industries. In these two fields reaction sintering has great opportunities due to its adequacy to modify the characteristics of the starting materials due to reactions. In this sense, reaction sintering of compacts constituted of mixtures of natural or recycled raw materials can be used to fabricate low cost ceramics with technological applications.

For instance, the reaction sintering of kaolin/phosphate mixtures has been proposed as feasible method to obtain hydroxyapatite and anortite based materials to be used in the electronics industry, for industrial heat exchangers and for biomedical applications (Chouia *et al.*, 2015).

Fig. 7 Linear shrinkage, $\Delta L/L_0$, vs. temperature for compacts of dolomite-zirconia used to process calcium-zirconate-magnesia composites. (a) Constant heating rate: Initial shrinkage is large and unstable. Low final shrinkage. (b) Constant shrinkage rate: Initial shrinkage is small. High final shrinkage. Reproduced from Booth, F., Garrido, L., Aglietti, E., *et al.*, 2016. CaZrO_3 -MgO structural ceramics obtained by reaction sintering of dolomite-zirconia mixtures. *Journal of the European Ceramic Society* 36, 2611–2626.

The most investigated waste sources are those suitable to be constituents of mixtures to obtain reaction sintered mullite-based materials. Some examples are: Fly ash, a by-product of the thermal power plants that contains relatively large amounts of SiO_2 and Al_2O_3 (Dey *et al.*, 2018); rice husk ash, a highly reactive source of SiO_2 (Serra *et al.*, 2016); and sillimanite and zircon sand, which is the industrial by-product generated during the extraction of rare earth compounds from beach sand (Kumar *et al.*, 2015).

A number of heating techniques different from the conventional furnaces and thermal treatment schedules are available to process high density materials with controlled grain size and they have also been applied to reaction sintering. Examples of these techniques and references where updated reviews on their use in ceramics can be found are spark plasma sintering (Franceschin *et al.*, 2017), microwave sintering (Karayannis, 2016), and hot pressing (Travitzky *et al.*, 2018).

The traditional approach to sintering is to optimize the time at the treatment temperature without paying attention to the characteristics of the heating rates employed in reaching the soak temperature. However, the effects of the non-isothermal portion of the heat treatment could determine the properties of the final product. The rate-controlled sintering, that has as independent variable the densification rate, has been proposed as alternative sintering method especially for systems in which reactions occur, such those involved in reaction sintering. In general, rate-controlled sintering firing profiles traverse slowly the permeable intermediate stages of shrinkage (density between 75% and 90% of theoretical), allowing the outgassing of the compact at relatively low temperatures, minimizing pore coarsening and grain growth. This alternative approach is especially adequate when using natural raw materials as carbonates. As an example, rate-controlled sintering has been used to fabricate fine grain and dense calcium zirconate-magnesia composites from mixtures of dolomite ($\text{CaMg}(\text{CO}_3)_2$) and zirconia (Booth *et al.*, 2016). As observed in Fig. 7(a), when the conventional constant heating rate is used, shrinkage variations at low temperatures are relatively large and non monotonous and total shrinkage is extremely low. When constant shrinkage rate is used as control variable (Fig. 7(b)), shrinkage at low temperatures ($<1200^\circ\text{C}$), where dolomite decomposition and the expansive formation of calcium zirconate occur, is low and total shrinkage at high temperature is very high.

To summarize, reaction sintering appears as a processing technique that allows reaching the main requirement of ceramics which is the microstructural control. A strict design of the composition and powder characteristics in the green compact together with the thermal treatment schedule is needed to obtain sintered materials with adequate microstructures. As it is now generally accepted in ceramic science and technology, for successful reaction sintering it is necessary to integrate raw materials selection, green processing and thermal treatment schedule in a single processing methodology.

Flash Sintering and Other Rapid Sintering Techniques

David Salamon, Brno University of Technology, Brno, Czech Republic

© 2021 Elsevier Inc. All rights reserved.

Innovative and novel sintering techniques are response to demand for sintering techniques that can effectively and predictably control the microstructure of powder pressed materials. It has been shown that the densification of powders by rapid heating and under external electromagnetic fields provides a finer control over the microstructure.

The idea to heat ceramics very rapidly is old, but it was for a long time believed that it is impossible due to the low thermal conductivity and thermo-shock resistance of these materials. Formation of a hard shell which then geometrically constrains the shrinkage and densification of the interior was reported during rapid rate sintering of nanocrystalline ZrO_2 –3 mol% Y_2O_3 powder (Chen and Mayo, 1996). Development of novel sintering techniques, such as Spark Plasma Sintering, demonstrated that under certain conditions ceramic materials can be sintered very fast (within minutes) without any gradient or crack formation (Shen *et al.*, 2002). Recently, interesting results have been achieved even faster (below 1 min) by so-called ultra-fast sintering, applying the electric current assisted/activated process (Zapata-Solvas *et al.*, 2015). Further research is conducting on the Electro-Discharge-Sintering (EDS) to achieve sintering below 1 s (Fais, 2018). Current heating techniques, which allow rapid (flash) sintering, are demonstrated in Fig. 1.

The current techniques demonstrated in Fig. 1 can be divided by an application of mechanical pressure (Fig. 1(a, b) versus Fig. 1(c, d, e, f)) or electric current (Fig. 1(a, b, c) versus Fig. 1(d, e, f)). An application of the mechanical pressure brings a possibility to sinter materials at lower temperatures and to obtain better microstructure. On the other hand, pressure-assisted techniques are more expensive and have volume/shape limitations. The second main difference between rapid sintering methods is an application of electric current or electromagnetic field (radiation). The electric current can directly pass through a material and sinter the ceramic material by Joule heating (also known as Ohmic heating). Joule heating is not the only reason for the rapid (flash) sintering; however, it's the most important reason for the Flash Sintering technique and Spark Plasma Sintering (SPS) of the electrically conductive materials (also for Capacitor discharge sintering). The electromagnetic field is used for the rapid heating during Induction sintering or Microwave sintering. Coherent monochromatic electromagnetic radiation (laser) is used to quickly heat up relatively small volume of the ceramic material at extremely high temperatures (thousands of degrees Celsius).

The common rapid sintering techniques suitable for the densification of advanced ceramic materials are:

- (1) Spark Plasma Sintering (SPS)/Field-assisted Sintering Technique (FAST),
- (2) Flash Sintering,
- (3) Capacitor discharge sintering (Electro-Discharge-Sintering or Electric Pulse Consolidation)
- (4) Selective Laser Sintering (SLS),
- (5) Induction sintering,
- (6) Microwave sintering.

Each method has several specifics and all of them require special equipment. A common feature is very rapid heating via the energy dissipation inside the sample or by the absorption from the outside source.

We can generally see two ways to divide these techniques:

- (1) Pressure-assisted and pressure-less techniques.
- (2) Electric current internal heating and heating by external electromagnetic field or laser.

Electric Current as a Source of Internal Heating

Electrical current can at certain conditions heat up ceramic materials similarly to heating a metal wire inside a conventional heater. Ceramic materials are typically electrical isolators at room temperature and only a few exceptions are borides or carbides. However, even very good electrical isolator such as aluminum oxide (alumina) can be sintered by Flash Sintering after doping and heating to high temperature with consequent application of high voltage (Cologna *et al.*, 2011). The second possibility how to make ceramic materials electrically conductive is to incorporate a conductive phase inside the isolating matrix. An example is the doping of the alumina matrix by carbon nanotubes and other additives before the flash sintering procedure (Muccillo *et al.*, 2019). The following description of methods using electric current as source of internal heating is based on the sintering of pure ceramic material, if it's not stated otherwise.

Flash Sintering

In flash sintering, a powder preform is slowly heated up, and then DC electrical field is applied directly to the specimen by a pair of electrodes. The specimen is densified in a few seconds during so-called "flash event" at significantly lower furnace temperature than that used during conventional sintering. This phenomenon occurs in several oxide systems, including yttria stabilized

Fig. 1 Simplified schema of the heat generation during rapid sintering of ceramic materials. (a) Spark Plasma Sintering, (b) Pressure-assisted flash sintering, (c) Flash Sintering, (d) Microwave sintering, (e) Selective laser sintering, (f) Induction sintering.

zirconia, magnesia doped alumina, strontium titanate, cobalt manganese oxide, titania and magnesium aluminum spinel, etc (Yu *et al.*, 2016). A characteristic feature of this process is that the sudden onset of sintering is accompanied by an equally abrupt increase in the conductivity of the specimen. The temperature of specimen is increasing as more electrical current can pass through the specimen, which eventually results in a thermal runaway and the specimen is densified in a few seconds. Immediately the power supply must be switched to current control due to limited current density provided by a power source. In the current control mode, the power expended in the specimen decline with the resistance of the specimen continues to fall. The total sintering time is just from a few seconds to several minutes and the temperature required for sintering in a just a few seconds can be extrapolated from the conventional time and temperature through the activation energy for the diffusion. One example of the flash event is shown in Fig. 2. The temperature of the specimen is not equal the furnace temperature, but its several hundred °C higher. The specimen temperature is a function of power dissipation calculated from thermal expansion as a function of power input (Baraki *et al.*, 2012) or by numerical simulation (Grasso *et al.*, 2011). The final specimen density is largely determined by the pre-set maximum current density, see Fig. 2, and that determine the specimen temperature at the steady state.

The flash event is characterized by three phenomenological effects:

- (1) The sample is quickly heated by an internal Joule effect.
- (2) The material shows a transition from insulator to conductor-like.
- (3) The sample starts to emit light – flash effect is observed (Biesuz and Sglavo, 2019).

Technical specification of the flash sintering apparatus

Possible experimental setups for the Flash Sintering are demonstrated in Fig. 3, the technique is relatively new and often are experimental setups modified. The critical part of the apparatus is the power source of direct electric current (DC) or alternating electric current (AC). This power source is modular and has to allow voltage and electric power setup. Voltage is usually from hundreds to thousands of Volts, depending on the electrical resistivity of sintered specimen. Beside possible high voltage, it's

Fig. 2 Examples of the measured linear shrinkage vs. furnace temperature curves for flash and conventional sintering of ZnO in air with a constant furnace ramp rate of $5^{\circ}\text{C min}^{-1}$. With an initial applied electric field of 300 V cm^{-1} , flashes started slightly below 600°C . The densifications occurred mostly within 30 s. The sintered densities depend on the pre-set maximum current (density) limits replotted after revision. Reproduced from Luo, J., 2018. The scientific questions and technological opportunities of flash sintering: From a case study of ZnO to other ceramics. *Scripta Materialia* 146, 260–266. Zhang, Y.Y., Nie, J.Y., Chan, J.M., Luo, J., 2017. Probing the densification mechanisms during flash sintering of ZnO. *Acta Materialia* 125, 465–475.

Fig. 3 Schematic figure of flash sintering apparatus with pressure-assisted or pressure-less technique. Note that anode and cathode are usually present, but flash sintering with AC is also possible.

necessary to regulate the electrical current during the flash event. Technically sensitive part is the connection between a specimen and the power source because the contact resistance can easily destroy part of the sample or connecting wires before the flash event. Application of mechanical pressure (Fig. 3 left) can help to decrease the contact resistance; however it brings also the shape limitation. On the other hand, pressure-less setup (Fig. 3 right) require careful green body preparation to avoid inhomogeneous electric current distribution. The flash event is observed by a camera and real temperature inside the sintered specimen is only estimated. Although the whole processing time is not very fast due to the slow external heating by conventional heating elements, the temperature is generally lower than during the flash event and it is a necessary step to make ceramic specimen conductive.

Fig. 4 SEM micrographs of (a) the cathode (–) side and (b) the anode (+) side of a fractured surface of a pure ZnO specimen flash-sintered with a low current density. The starting particle size was slightly smaller than 0.5 μm and limited grain growth occurred at the cathode side, while the grain size doubled at the anode side. Reproduced from Zhang, Y., Jung, J.-I., Luo, J., 2015. Thermal runaway, flash sintering and asymmetrical microstructural development of ZnO and ZnO–Bi₂O₃ under direct currents. *Acta Materialia* 94, 87–100.

Mechanism of flash sintering

The proposed mechanisms for flash sintering try to explain both mass and charge transport. Since 2010 four mechanisms were proposed:

- (1) Joule heating of the specimen by the current flow at grain boundaries that enhances grain boundary diffusion and electrical conductivity; (Cologna *et al.*, 2010).
- (2) The formation of an avalanche Frenkel pairs driven by the applied field and enhancement of mass transport by the defect population (Naik *et al.*, 2014).
- (3) Selective Joule heating and a non-linear interaction between intrinsic fields (space charges) and the applied field that produces “a catastrophic change in self-diffusion at grain boundaries” (Cologna *et al.*, 2010).
- (4) Formation of particularly reduced structures and defect catastrophe that includes unusual generation of electrons, holes and point defects, resulting in sintering, electronic conductivity, electroluminescence, and phase transformations (Jha *et al.*, 2016). If the material is partially reduced its electrical properties would change (Bonola *et al.*, 1991) leading to an increase electronic contribution to conduction or it could change the activation energy for cations (Qin *et al.*, 2016) diffusion leading to non-conventional grain growth (Kim *et al.*, 2011; Qin *et al.*, 2016) and densification phenomena.

The mechanisms driving the rapid densification will be further clarified by modeling work, advanced in situ analysis techniques and by established theories applied to electric current assisted/activated sintering techniques (Yu *et al.*, 2016).

Generally, it is possible to define flash sintering as a current assisted sintering technology characterized by rapid densification (matter of few seconds-minutes) and by the simultaneous observation of the flash event, including a thermal runaway of internally generated Joule heating, electrical conductivity abrupt drop and strong bright light emission. The flash event is reproduced when specific onset electric power dissipation is reached in the ceramic body, typically, in the range 10–50 mW mm^{-3} . Often inhomogeneous sintering is observed on cathode and anode, see Fig. 4. This cathode-side abnormal grain growth can be explained from the electric-potential-induced accumulation of electrons and an associated oxidation reaction to form excess cation vacancies at ZnO grain boundaries that promote interfacial diffusion (Tuller, 1999). Other explanations are potential-induced abnormal grain growth (Kim *et al.*, 2011) or the idea of grain boundary complexion transitions (Cantwell *et al.*, 2014).

- Advantages: No shape limitation, various atmospheres, pressure/pressure-less alternative, unique microstructures, energy efficient, low investment.
- Disadvantages: Technically difficult electrode connections, low control over the process, often inhomogeneous sintering, depends on green body quality.

Spark Plasma Sintering (SPS) or Field Assisted Sintering (FAST)

The Spark Plasma Sintering (SPS) technique, also known as plasma activated sintering or field-assisted sintering technique (FAST), requires mechanical pressure, specific sintering die, and the application of a high pulsing DC current. The word “plasma” is often misleading, because this sintering technique is not derived from a plasma generating machine and even the presence of plasma inside the sintered powders is questionable.

The SPS is especially useful for densifying hard to sinter ceramics including carbides, nitrides, borides and their composites. Furthermore, it is also promising with regard to achieving dense materials with nano and submicrometric structure in nano-powder based materials.

Fig. 5 Simplified schema of the spark plasma sintering apparatus with focus on the sintering die.

Technical aspects

The technique provides direct contact of heating elements (sintering die) with the samples, very rapid heating/cooling rates (several hundreds of $^{\circ}\text{C min}^{-1}$), and uniaxial mechanical pressure. A part of the SPS/FAST apparatus is shown in [Fig. 5](#).

Technical differences between SPS, FAST and other apparatus are significant, but all have a source of pulses of direct current (DC) described by ON:OFF ratio. Producers of SPS apparatus can have even different electrical source of DC pulses with various possibilities ON:OFF pulse setting and various “sharpness” of the electric pulses. The SPS (Fuji, Japan) have the very reliable long-life source, but with less sharp pulses and with limited range of possible pulse frequencies compare to the FAST (FCT, Germany) apparatus. Some producers can have very sharp pulses (Thermal technology, USA), however, the impact of the pulse setting is still debated. All SPS sources have relatively low voltage (up to 12 or 24 V depends on a producer) and very high electric current (limited to 1000–50000 A depends on a model), this limits the use of SPS apparatus for internal heating of low electrically conductive samples. On the other hand, heating of the graphite sintering die can be very fast up to $1000^{\circ}\text{C min}^{-1}$ due to possible high current density.

Every SPS apparatus uses graphite sintering dies with good electrical conductivity and mechanical strength. The shape design is different and FAST apparatus has one extra control point for the temperature measurement, however this hole influences the heat distribution inside the punch. Graphite needed for SPS tools has to provide excellent electrical and mechanical properties and some companies produce special “SPS-ready” graphite. Mechanical properties of graphite limit an applied mechanical pressure to approximately 100 MPa for the standard setting, however special die settings including “small die in big die” allows mechanical pressure up to 1000 MPa ([Anselmi-Tamburini et al., 2006](#)). However, this is limited to small diameters of the sample and relatively low temperatures. High-temperature stability of the graphite allows achieving temperature above 2200°C inside the SPS die, but atmosphere inside the sintering chamber is limited to inert gases. The most common atmosphere is “running vacuum”, that means constantly running vacuum pump during the sintering process (usually 5–10 Pa). Due to the tightly closed graphite sintering die (using graphite paper as sealing medium, see [Fig. 5](#)), it is possible to sinter also materials decomposing in vacuum such as silicon nitride, etc. ([Shen et al., 2002](#)). Disadvantage of the graphite dies is presence of carbon and reductive environment inside the powder during the sintering process. Carbon is spread also by gas phase and therefore it is very difficult to avoid the contamination just by isolating the sintered powder. Several approaches can be used such as.

- (1) Lower the sintering temperature (higher contamination with increasing temperature).
- (2) Carefully remove residual oxygen from inert gas between the sintered powder, particle size also plays a role ([Bertrand et al., 2014](#)).
- (3) Use sintering additives reacting with residual carbon and forming removable gas ([Meir et al., 2009](#)).
- (4) Use a platinum foil instead of a graphite foil to make a carbon free environment ([Biswas et al., 2016](#)).

Spark Plasma Sintering was originally referred as sintering at lower temperatures compared with conventional techniques. Nowadays, numerical modeling (primarily finite elements) supported by experimental results demonstrated that real internal temperature is higher than measured (Vanmeensel *et al.*, 2005). Models predicting the real temperature of sintering dies are already available (Li and Shen, 2015; Vanmeensel *et al.*, 2005) and show variation between electrically conductive and not conductive samples. The electrically conductive samples are internally heated by Joule heating and temperature inside the sintered samples is much higher than measured outside. On the other hand electrically not conductive samples have the hottest part close to the sintering die, but measured temperature is from outside of the sintering die. The temperature gradient inside the sample can be limited by design of the sintering die (tailored current flow) or by adding isolating graphite wool (see Fig. 1). However, homogeneous and crack-free microstructures are obtained after spark plasma sintering (Orrù *et al.*, 2009) even when the thermal gradient is extremely high. A number of explanations of how a thermal gradient can be balanced have been proposed. Firstly, plasma is generated inside the sintering sample. Secondly, internal heating is present when the electric current passes through the sample. Thirdly, high mechanical pressure significantly enhances the heat transfer from the outside to the inside of the sample. All three explanations are controversial (Hulbert *et al.*, 2008; Orrù *et al.*, 2009; Salamon and Shen, 2008). Pressure-less SPS indicates that the mechanical pressure or DC current passing through samples are not crucial parameters for rapid heating in the whole volume (Salamon *et al.*, 2012). Furthermore, an advantage of this technique is the possibility of flexible geometries of a thermal radiation source by the machining of sintering dies (Li and Shen, 2015). In addition, application of very low mechanical pressure brings significant advantages for sintering of porous materials from hollow particles/spheres when internal porosity is preserved after preparation of machinable compacts (Dudina *et al.*, 2019).

- (1) Advantages – Unique densification possibilities, reductive environment or inert atmosphere, mechanical pressure, fast and low energy process,
- (2) Disadvantages – Shape and size limitations, presence of carbon, unique and expensive equipment.

Capacitor Discharge Sintering (CDS)

Capacitor discharge sintering (Fais, 2010) is an electric current assisted sintering (ECAS) technique. The technique is based on storage of electromagnetic energy in a high voltage capacitor bank, and discharge on one step into the sintering apparatus at low voltage (below 30 V) and high current through step-down transformers (sinters) on a pre-compacted powder compact. The sintering die and Electrodes are technically similar to those employed in field-assisted sintering techniques (SPS, FAST) and single electromagnetic pulse sintering technologies.

Nowadays, only samples containing metals were compacted and ceramics trials on electrically conductive ceramics (such as TiB₂) have been made but sintering them has not been completely successful. Electrically insulating ceramics such as oxides do not seem to be sinterable since the dies are made of insulating materials to force the current flow through the powders and no preheating is applied. Experiments showed that combining insulating dies and electrically conductive ceramic powders, although the electric potential increases to 50 V on the compacted powders, barely any current will flow and the material will not sinter. (Fais, 2018).

- (1) Advantages: Whole process is very fast, energy efficient, mechanical pressure, no impact of atmosphere,
- (2) Disadvantages: Shape limitation, unique equipment, difficult to control, limited to ceramic-metal composites.

Heating by External Electromagnetic Field

Selective Laser Sintering (SLS)

Selective laser sintering or melting is the mostly used as a rapid prototyping method where a solid object is built by joining powder particles together via a focused laser beam. In the SLS process, a thin layer of powder is spread across a platform by a blade or a roller mechanism. A modulated laser writes the computer-aided design (CAD) data selectively on the powder bed so that only the particles in an area with the cross-section of the object are fused by laser energy. However, for direct sintering of most ceramic powders the power of the laser beam is not sufficient, because ceramic materials require very high energy densities, approximately an order of magnitude higher than those required for metals (Hayden, 2006). Furthermore, ceramic/laser beam interaction often causes melting, evaporation and ablation rather than sintering. Then the laser beam is used for precise machining of ceramic parts rather than for sintering (Perrie *et al.*, 2005). Nevertheless, the recent development of the laser beam control brings unique opportunities for achieving hierarchically structured heterogeneities and non-equilibrium phase assemblages in bulk ceramics (Qian and Shen, 2013). The residual thermal stresses must be controlled and the dimensional tolerances must achieve micron levels to use the laser for microstructure tailoring. A possible strategy besides sintering is the melting of crystalline ceramic materials and its recrystallization during the cooling process. Usually, complex structural hierarchies are formed due to wide energy dissipation (Wang *et al.*, 2015) and many challenges have to be overcome to use the SLS as a rapid prototyping method (Sing *et al.*, 2017):

- (1) Powder layer deposition – distribution of particle size has to be tailored to increase flowability and decrease powder agglomeration.
- (2) Laser interaction with powder – suitable wavelength and power are necessary for each composition of powder.

- (3) Melting and consolidation mechanism – melted ceramics have certain viscosity and bubbles can easily appear.
- (4) Thermal and residual stresses analysis – sintered parts easily contain cracks therefore thermal and residual stresses have to be managed.
 - Advantages – Controlled wavelength and energy, localization of exposed area, possibility to implement laser into various environments (conventional furnace, SEM etc.), energy efficient.
 - Disadvantages – Limited number of wavelengths, high price for one unit, limited area of exposure at the same time, difficult to control (often melting), thermal stresses, no mechanical pressure.

Induction Sintering

Induction sintering is done by a non-contact heating process. It uses a high frequency electric field to heat up electrically conductive materials. Since it is a non-contact method, the heating process does not contaminate the material being heated. It is also very efficient since the heat is actually generated inside the sample, and the process is often used for metallurgical heat treatment (quenching, hardening, brazing), surface coating or melting (Davies, 1990). Advanced ceramics, which are usually non-electrically conductive, can be sintered by induction heating of a sintering die or susceptor, and in this case the internal heating of a sample is negligible (Kim *et al.*, 2007). Induction sintering is one of the rapid sintering alternatives for ceramic materials with dopants, however more often the induction heating is used for rapid heating of graphite sintering die. The induction heating allows very high heating rates similarly with Spark Plasma Sintering method and rapid densification was also observed (Kim and Khalil, 2006).

- (1) Advantages: Possibility to penetrate deep inside the ceramic green body, energy efficient,
- (2) Disadvantages: Necessity of using dopants (susceptor), limited options for exposure areas and intensity of the field, high price of the unit.

Microwave Sintering

Microwave energy is a form of electromagnetic energy with a frequency range of 300 MHz to 300 GHz. Microwave heating is a process in which the materials couple with microwaves, absorb the electromagnetic energy volumetrically, and transform it into heat. Microwave heating contrary to conventional heating generates heat within the material first and then heats the entire volume of the furnace (Yadoji *et al.*, 2003). The various heating regimes lead to the development of global and localized thermal instabilities and the role of the temperature dependence of the materials dielectric properties (in the microwave range) in the formation of instabilities was also demonstrated (Kulumbaev *et al.*, 2007). The optimization of microwave distribution requires extensive process modeling. The both the fundamentals and numerical calculation methods demand extensive computation resources for the simulation of large multimode microwave cavity applicators (Rybakov *et al.*, 2013). Nowadays microwave heating is often applied in hybrid mode when microwave power source is combined with conventional heating elements. Besides advantages, microwave sintering is not widely used due to the complexity of microwave heating and its implications for large objects.

Recently, microwave heating was applied for flash sintering of ceramics, where microwave heating with high absorbed power per unit volume of material ($10\text{--}500\text{ W cm}^{-3}$) is presented (Bykov *et al.*, 2016). During microwave heating from the core of the sample the particles melt and form the liquid phase inside. In effect, a densification front propagates from core of the sample to its periphery, producing a fully dense ceramic material in a very short time. Microwave flash sintering is a novel process and the authors suggest that the mechanism of ultra-rapid densification are similar or even identical with DC or low-frequency AC flash sintering (Bykov *et al.*, 2016).

- (1) Advantages: No shape limitation, various atmosphere, fast densification, low energy consumption, low investments.
- (2) Disadvantages: Sensitive due to local instabilities, problems with large samples.

Summary and Perspectives

Rapid sintering techniques are due to the recent fast development in a group of novel sintering techniques. These methods should predictably and effectively (low energy consumption and short time) control ceramic microstructure during the sintering process. However, nowadays it's still very challenging to control microstructure during such fast sintering. Microwave, Induction and Spark Plasma Sintering already have several specific applications, where the energy saving and unique microstructures are the main benefits. Capacitor discharge sintering is originally designed for specific applications and the amount of research carried out is relatively small because a unique device is needed.

Selective Laser Sintering, often design as a rapid prototyping method, is changing quickly with improvements in the laser technology, but several challenges have to be overcome to achieve expected industrial applications (Sing *et al.*, 2017). Multi-disciplinary approach and long-term research should be applied to study selective laser sintering (or melting) for industrial rapid prototyping of ceramic materials, but a wide range of applications and gained benefits are a strong motivation.

Flash sintering by an electric current is very new in the field of ceramic materials and research has boomed since 2010 (Cologna *et al.*, 2010). A reason is the relatively simple and low cost apparatus with a large variation of experimental settings. Therefore, hundreds of valuable articles have been published and nowadays basic theoretical knowledge is available. Due to unique possibilities, future applications are expected to follow in the next decade.

Spark Plasma Sintering

Umberto Anselmi-Tamburini, University of Pavia, Pavia, Italy

© 2021 Elsevier Inc. All rights reserved.

Introduction

The term Spark Plasma Sintering (SPS) is generally used to identify a sintering technique involving the contemporaneous use of uniaxial pressure and high-intensity, low-voltage, pulsed current. In general terms, SPS can be considered a modification of hot pressing, where the furnace is replaced by the mold containing the sample, that is heated by a current flowing directly through it and eventually through the sample. However, since there is no general agreement on the details of the technique, an unequivocal definition of the SPS and its associated procedures cannot be defined (Grasso *et al.*, 2009; Orrù *et al.*, 2009). The name SPS itself has been often disputed as, despite several attempts, the presence of plasma and electric discharges during the process it has never been proved unequivocally.

SPS has been receiving growing attention in the last two decades due to its remarkable effectiveness, allowing to obtain fast sintering and densification, particularly in the case of materials considered hard to sinter, such as extremely refractory materials, metastable phases or nanomaterials. For some of these materials, SPS has already become the sintering technique of choice.

SPS belongs to a quite extensive group of techniques involving the use of electric current for the sintering of materials. Some of these techniques have been introduced, and found widespread application, since the beginning of the last century, particularly for metallic materials. More details on this historical evolution can be found in recent reviews (Olevsky and Dudina, 2018; Guillon *et al.*, 2014; Munir *et al.*, 2011; Orrù *et al.*, 2009). The most distinctive characteristics of SPS, represented by the use of pulsed DC, appeared originally in a patent by Inoue in the mid '60 of the last century (Inoue, 1966), while the term SPS was introduced later on, by the Japanese producers of the first commercial machines. In the beginning, the technique found application mostly in Japan and in a few other far-east countries. The diffusion in western countries, mainly in research institutions, started in the mid '90 of the last century and spread rapidly in the industrial environment.

Machines similar to SPS, but using electric currents presenting a time pattern different from pulsed DC have also been proposed over the years. In particular, the use of plain DC or AC has been suggested. Although there is no generally recognized nomenclature, such techniques are usually referred to as 'Field Assisted Sintering' (acronym FAST) (Orrù *et al.*, 2009). However, a thorough investigation on the role played by the current pattern in determining the characteristics of the sintering process has never been presented. Available indications are suggesting that the current pattern might play a significant role only in a few specific cases, while the main characteristics remain quite similar. For this reason, the coupled acronym SPS/FAST is often used in recent literature to indicate all pressure-assisted, current-assisted, rapid sintering techniques.

General Characteristics

When compared to other more conventional sintering techniques, such as pressureless sintering, hot-pressing, and hot isostatic pressing, SPS is characterized by some distinctive features, represented by the combination of faster heating rates, shorter sintering cycles, lower sintering temperatures, and reduced grain growth. SPS systems can typically operate using heating rate in the range of hundreds of degrees per minute, but values above $1000^{\circ}\text{C min}^{-1}$ can in principle be achieved. These values are between one and three orders of magnitude higher than in conventional sintering and allow for a drastic reduction in the length of the sintering cycles. Besides faster heating rates, the technique also allows shorter sintering times. The two effects combined allow the reduction of typical sintering cycles to a few minutes, which compares with the few hours generally used in conventional sintering. This increase in sintering efficiency allows also reducing the sintering temperatures, sometimes hundreds of degrees, particularly in the case of very refractory materials. This decrease in the sintering temperature produces a general reduction in grain growth, producing materials characterized by smaller grain size and better mechanical properties.

Experimental Setup

Machine Layout

As mentioned before, the general layout of SPS systems presents several similarities with that of a hot-pressing. A simplified schematic is reproduced in Fig. 1. The sample is placed in a mold, or die. No preliminary forming of the material to be sintered is required, as it is generally introduced in the mold in powder form. The mold is warmed up through the passage of a high intensity/low voltage electric current directly through it. A uniaxial pressure is applied by an hydraulic system. These pistons also act as electrodes, supplying the high-intensity current that must flow through the die and the sample. The hydraulic pistons are water-cooled in order to protect them from the heat deriving from the die. The pressure is controlled by a PID feedback system in order to keep it constant during the sintering process. In fact, the sample and the die experience a considerable change in volume during

Fig. 1 Schematic of a typical SPS system. Reproduced from Munir, Z.A., Quach, D.V., Ohyanagi, M., 2011. Electric current activation of sintering: A review of the pulsed electric current sintering process: Electric current activation of sintering. *J. Am. Ceram. Soc.* 94, 1–19.

the process, that, if not properly compensated, can result in significant changes in the applied pressure. An example of the overall variations in the linear dimension of the die/sample assembly during a typical SPS sintering cycle is presented in Fig. 2. The actual sample volume contraction due to the densification cannot be directly obtained from these curves unless a calibration based on the thermal expansion characteristics of the tool and of the fully densified samples is performed first.

The most distinctive feature of SPS systems is represented by the use of pulsed electric current. As mentioned in the introduction, this current can present different characteristics. Typically low-voltage (<10 V) and high-intensity currents (between 1 and 50 kA) are used. Different time patterns can be used. In early SPS systems, the current was always pulsed DC, presenting pulses of constant duration (about 3 ms) that could be assembled in predefined sequences (Fig. 3). More recent machines offer more flexibility, allowing to define the duration of the pulses, the delay time between them, the total number of pulses in the sequence, and the number of pulses on and off. In some cases, plain DC or AC can also be used.

The temperature control is generally realized using a thermocouple or a pyrometer, depending on the maximum required temperature. The thermocouple is usually positioned in a small hole drilled halfway through the lateral wall of the die body. A larger hole (few mm in diameter), acting as a black-body cavity, is used in the case of pyrometer reading. Alternative positioning for the pyrometer and the thermocouples have been suggested. The most common involves positioning on the central axis of one of the punches of the die. This axial positioning is more accurate but it is less used because more complicated to setup.

Experimental Procedure

A typical SPS process involves the following sequence of operations. The starting material, generally in the form of fine powders, is placed in the die. The characteristics of this die must be selected on the basis of considerations that will be discussed in the following sections. The die is then positioned between the two hydraulic pistons and the uniaxial pressure is applied. Different kinds of pressure cycles can be used. In most cases, the pressure is applied at the beginning of the process and is maintained constant throughout the sintering cycles. A common alternative is to apply only a minimum pressure at the beginning and the full pressure only when the sample reaches the target sintering temperature. The system is evacuated to a low vacuum (generally few Pa). The main purpose of the vacuum is just to protect the graphite tools from oxidation and to reduce the thermal conduction. An atmosphere of inert gas can be used when overheating is not an issue. The use of an inert atmosphere might also help to reduce the evaporation of volatile samples. Air, on the other hand, requires an oxidation-resistant tool material, such as SiC. The sintering cycle is then started. The temperature profile generally involves a linear ramp to the target temperature with a heating rate between 50 and $200^{\circ}\text{C min}^{-1}$. More complex temperature cycles can be used in the case of reacting or outgassing materials. At the end of the sintering process the heating is turned off and the pressure released. In most cases, the sample is let to cool naturally. This involves a very rapid initial cooling, in the range of several hundreds of degrees per minute. The sample can be removed after 20–60 min, depending on the type of machine and the size of the sample.

Fig. 2 Example of the variation in the linear dimension of the SPS tool during a typical densification experiment. The experimental curve indicates the overall modification. The baseline indicates the changes due only to the thermal expansion of the die and the fully dense sample. The corrected line is obtained subtracting the two previous curves and indicates the actual change in the dimension of the sample due to the densification process. Reproduced from Anselmi-Tamburini, U., Garay, J.E., Munir, Z.A., 2005. Fundamental investigations on the spark plasma sintering/synthesis process. *Mater. Sci. Eng. A* 407, 24–30.

Temperature, Current and Stress Distribution

A crucial aspect of SPS technology is represented by the possible presence of inhomogeneities in the final product deriving from an uneven distribution in temperature, current density, and mechanical stress during the densification process. This point was largely underestimated in the early applications of the technique, but has been clarified in subsequent investigations, thanks mostly to numerical modeling (Muñoz and Anselmi-Tamburini, 2013; Olevsky and Froyen, 2006; Olevsky *et al.*, 2012; Pavia *et al.*, 2013).

The most critical aspect is represented by the presence of temperature inhomogeneities. These inhomogeneities represent the downside of otherwise positive characteristics of SPS, represented by its fast response time and low thermal inertia. The absence of a furnace makes the control of the temperature distribution much more challenging. In SPS systems the heating of the sample derives only from the current flowing through the die and the sample itself. The current distribution, however, could be quite complex, depending primarily on the die geometry and the electrical properties of the sample. The portion of the punches sticking out of the die, for instance, usually represents the part of the tool with the smaller cross-section and the higher current density; as a result, these parts tend to heat up faster and to remain hotter throughout the process. Within the die body, the current densities can vary considerably, depending on the sample conductivity. In the case of samples presenting an elevated electrical conductivity most of the current flows through the sample itself, with only a minimal amount of current flowing in the graphite walls of the die (see Fig. 4). However, since the joule heating is dependent also on the resistivity of the material, regions with low resistivity give a little contribution in terms of heat generation (Fig. 5). On the other hand, in the case of non-conducting samples, a much more complex current distribution is expected, with the higher current densities being observed within the die walls and on the edges of the sample.

Heat losses contribute also in determining the temperature distribution. Since SPS experiments are generally performed in a vacuum, at low temperatures the only significant heat loss is due to the conduction along the die punches towards the cooler hydraulic cylinders. At higher temperatures, above 700–800°C, radiation losses tend to dominate. To further complicate the picture, it must be considered that the electrical properties of the die and of the sample change with temperature and the extent of the densification process. It is not unusual for metallic samples, for instance, to present very low electrical conductivity at the beginning of the densification process, when still in powder form, and become very conductive when the densification is completed. All these factors contribute to producing complex and difficult to predict temperature distributions. Experimental investigations on these aspects have been quite limited, but extensive numerical modeling has been used to clarify the influence of

Fig. 3 Example of a typical current pattern used in SPS machines of the first generation. The pulses width is constant (3 ms), while the number of pulses on and off in the sequence can be modified (see boxes). Reproduced from Chen, W., Anselmi-Tamburini, U., Garay, J.E., Groza, J.R., Munir, Z.A., 2005. Fundamental investigations on the spark plasma sintering/synthesis process. *Mater. Sci. Eng. A394*, 132–138.

the various parameters on the temperature uniformity within the samples (Muñoz and Anselmi-Tamburini, 2013; Olevsky and Froyen, 2006; Olevsky *et al.*, 2012; Pavia *et al.*, 2013). These studies evidenced, for instance, as the temperature distribution is strongly dependent on the size of the sample. Samples with small diameter, up to 1–2 cm, always present quite limited temperature inhomogeneities. In these samples the radial temperature distribution is generally characterized by a maximum in the center of the sample, which can be more or less evident depending on the electrical properties of the sample. Obtaining a uniform temperature distribution becomes challenging in the case of larger samples, presenting a diameter of 5 cm or higher. For very large samples temperature differences in the range of tens of even hundreds of degrees between the center and the edges of the samples have been reported. Some actions can be taken to mitigate such inhomogeneities. First and foremost, an appropriate design of the die must be optimized through numerical modeling. In some cases, a reduction in the heat losses can be helpful, particularly if very high temperatures are involved. It is a quite common practice, for instance, to wrap the dies with carbon or alumina felt in order to reduce heat losses by radiation. Although this might help in the case of radial temperature distribution presenting a maximum in the center, it might be detrimental when, as in the case of non-conducting samples, the temperature maximum tends to be located on the sample edges.

Besides temperature, stress might also present non-uniform distribution within the sample. This point has been less investigated also because it is very difficult, if not impossible, to monitor the stress distribution within the die and the sample during the process. The available information derives only from numerical modeling. A relevant point evidenced by these studies is the role of the difference in thermal expansion between the sample and the die. Materials with thermal expansion larger than graphite, such as metals, experience a significant increase in the stress in the proximity of the sample edges. The role of these stress distribution on the microstructure of the densified materials has never been thoroughly investigated, although, in principle, might be relevant. On the other hand, differences in thermal expansion might induce large stress in the peripheral region of the sample during the cooling, which is generally fast and uncontrolled in typical SPS processes, producing fracture in brittle materials.

Tooling

The choice of the material used as a die represents a critical point of SPS technology. In order to be effective, the die must present the appropriate combination of thermo-mechanical-electrical properties within the temperature range used for the densification process. Regarding the mechanical stresses, it must be considered that while the punches experience only compressive stress, the body of the die experience a complex, mostly tensile stress. The die must also present low reactivity towards the sample and suitable electrical properties. This last requirement implies an electrical conductivity that is high enough to allow high-intensity current to flow, but low enough to produce a significant Joule heating. Although ideal for most applications, graphite presents several limitations. Even the best graphites, characterized by high density, low porosity, and small grain size, present a quite limited compressive strength (< 150 MPa). This limitation reduces the maximum uniaxial pressure that can be applied to the sample. Another obvious limitation of graphite is related to the possible reaction/contamination of the sample. Several transition metals can, in fact, form very stable carbides. Besides altering the chemical composition of the surface of the sample, this might result in the formation of a strong bond, that in some cases can make even impossible to remove the sample from the die without breaking it. In these cases some sort of a superficial lining is necessary. Graphite contamination can also derive from the release of graphite powders during the sample loading or from high-temperature fast diffusivity of graphite in some materials. Finally, it must be considered that graphite dies can be used only in vacuum or in an inert atmosphere. This environment, on the other hand, can be damaging towards some kind of samples, as they result exposed to a very strong reducing environment during the sintering process. Low-stability oxides represent a typical case, as they can be partially or totally reduced during SPS processing. Unfortunately, alternatives to graphite are quite limited. When high temperatures are involved, the only materials presenting mechanical and chemical properties better than graphite are silicon carbide and tungsten carbide. Silicon carbide also represents the only alternative when oxidizing atmosphere must be used. SiC and WC dies, however, are very expensive, particularly when large samples are involved. Furthermore, being a semiconductor, the electrical resistance of SiC decreases significantly with temperature, complicating the temperature control. Metallic dies, such as high-strength, low-conductivity steel, can be used only for low-temperature

applications, where plastic deformation and creep are not a concern. The same considerations hold for cemented carbides (hard metals) presenting much higher compressive strength, but only at temperatures below 700°C. A combination of ceramic dies with conducting punches is sometimes used, although this requires the sample to be conductive.

Microscopic Mechanisms

The remarkable ability of SPS to produce fast densification generated, from the beginning, an intense debate about the underlying microscopic mechanisms. Several excellent reviews are available in the literature discussing this topic in detail (Anselmi-Tamburini *et al.*, 2013; Cao *et al.*, 2019; Olevsky and Dudina, 2018; Garay, 2010; Grasso *et al.*, 2009; Guillon *et al.*, 2014; Munir *et al.*, 2011, 2006). It must be noted, however, that the number of proposed microscopic mechanisms is quite large and single out the importance of each one of them proved to be very difficult. The number of available experimental and modeling approaches that can be used to test their relevance is, in fact, limited. In general, it can be concluded that there is probably not a single process that is responsible for all the SPS characteristics, but a number of them, that vary depending on the thermal, electrical and chemical characteristics of the material to be sintered. It also often forgotten that the growth of interest towards SPS coincided with the increased availability of materials in the form of nanopowders. Due to the fast heating rates, SPS can take better advantage than conventional sintering of the intrinsic faster sinterability of the nanopowders. However, the understanding of the basic mechanisms is still largely a work in progress, which is crucial for bringing this technique on a solid basis and it is expected to continue receiving large attention in future investigations.

Arc and Plasma Discharges

In early works it was suggested that the unique SPS characteristics derived entirely from the type of pulsed current used during the process (Tokita, 1999). Short pulses of high-intensity current were, in fact, believed to generate local conditions enhancing the atomic mobility through the formation of plasma, or electric discharges, in the small volumes between the grains. Although it was believed that these phenomena were active mostly in the early stages of the process, their beneficial effects were supposed to influence also the late stages of the sintering process. This interpretation enjoyed a large fortune and is still often presented today when discussing the SPS characteristics. Later investigations, however, questioned this interpretation evidencing some major inconsistencies it implies (Hulbert *et al.*, 2008a). Most types of vacuum discharges, such as arc, spark and glow discharges, require high voltages, that are not compatible with the SPS experimental conditions, generally characterized by voltages below 10 V. Only arc discharges can in principle be sustained under low voltages, but they require high electrical conductivity, while SPS is very effective even in the case of insulating ceramic materials. More importantly, the presence of plasma or electrical discharges was never substantiated by any sound experimental evidence, with few exceptions limited to some specific situation (Bonifacio *et al.*, 2013; Saunders *et al.*, 2015; Zhang *et al.*, 2014). So, it became more and more difficult to justify the characteristics of the SPS considering only a single mechanism.

Applied Electric Fields

The possible influence of the applied electric fields plays a central role in the discussion on the mechanisms responsible for the SPS characteristics. This interest is suggested by the consideration that SPS processes involve the use of very high current intensities, up to several kA. In reality, it must be considered that the intensity of the electric field and the currents experienced by the sample are usually quite modest. As evidenced by Fig. 1, the graphite die and the sample can be seen as two electric loads in parallel to each other. Since the electrical resistance of the die is quite low, the voltage drop across the die and the sample is always limited to a few mV, regardless of the voltage generated by the power supplier (usually below 10 V) and of the sample resistivity. For the same reason, the current flow is usually mostly confined within the die components, except in the case of very conducting samples, such as metals in the late stages of densification. These considerations drive to the conclusion that the influence of the electric fields and currents on the densification mechanisms involved in SPS processes, has probably been often overstated.

However, applied electric fields can indeed modify considerably the atomic mobility in solid materials. The most direct evidence is observed in ionic materials, where applied electric fields can induce the movement of the constitutive ions (electromigration), or produce polarization when the electric charges are not free to move. Both phenomena have been largely investigated in solid state science and have the potential to produce profound modifications in the sintering mechanisms. Despite that, the possibility to enhance or decrease the rate of sintering and densification of ionic materials through the application of an electric field is still largely unexplored. However, it must be considered that the influence of electrotransport can be quite complex and depends strongly on the characteristics of the material under consideration. Not in all cases, in fact, the ionic flux produced by the applied electric field can produce the kind of material transport required in sintering. Complete decomposition and reconstruction of crystallographic sites are required, not just the movement of one component. However, in ionic materials intense fluxes of single charged elements might induce mobility of other elements through correlation effects. A typical example is represented by the correlation between electrons and ions movements in mixed conductors. In the case of dielectric materials, polarization might play a significant role, particularly when very small grains are considered. In the point of contact between small particles the polarization effect might produce an amplification of the applied electric field that might extend to several orders of magnitude, producing extreme localized conditions that might enhance atomic mobility.

Another phenomenon associated with applied electric fields often mentioned in SPS literature is electromigration. This term generally relates to the transport of material in metals when elevated electronic current densities ($> 1000 \text{ A/cm}^2$) are present. Electromigration has been extensively investigated for its implication in microelectronics but has never been well characterized in materials presenting complex microstructures, such as powder compacts in the early stages of sintering. Its association with SPS is suggested by the intense electric currents involved with this technique although, as mentioned earlier, the local current densities experienced by SPS samples are usually orders of magnitude below the threshold required for the electromigration phenomena to become evident. Direct experimental evidence on the role played by electromigration in SPS sintering, is limited to model systems where all the current is forced to flow through the sample (Frei *et al.*, 2007).

Other physical effects that are often associated with the presence of applied electric fields in SPS are elastoplasticity, ponderomotive forces, electromagnetic ‘pinch’ effect, and Peltier effect. The relevance of these effects on the actual sinter process has still largely to be determined.

Applied Pressure

SPS belongs to the group of the pressure-assisted sintering techniques, as hot-pressing and hot-isostatic pressing. Similar arguments relative to the influence of the pressure on densification apply to all these techniques. The pressure is generally expected to enhance densification through plastic deformation and grain boundary sliding. These processes reduce the pore volume and the dependence of the densification from bulk diffusion. As a result, also grain growth is generally reduced applying pressure. As noted before, in SPS the maximum applied pressure is limited by the compressive strength of the tooling. Graphite dies do not allow pressures above 100–150 MPa. High-pressure modification of the conventional technique has been presented and be described later on.

Heating Rates

Another typical feature often associated with SPS superior sintering capability is represented by the possibility to use very high heating rates. As mentioned before, in the SPS practice it is quite common to use heating rates in the range of hundreds of degrees per minute. These values are between one and three orders of magnitude higher than in hot-pressing, hot-isostatic pressing, or even in conventional pressureless sintering. Such a relevant increase in the heating rate has a profound influence on the sintering process. Although in general the heating rate does not modify the densification mechanisms, it can influence the relative importance of competing processes presenting different activation energy. During sintering, in fact, several mass transport processes are active at the same time. We can mention, in order of increasing values of activation energy, surface diffusion, grain boundary diffusion, power-law creep, and bulk diffusion. Surface diffusion is a non-densifying process, as it cannot contribute to the growth of the intergranular necks. It contributes significantly, on the other hand, on grain growth. As a result, long exposure of the green compact at temperatures where surface diffusion is dominating ($0.25\text{--}0.4 T_m$) might result in a microstructure characterized by poorly sintered large grains and large pores, reducing the effectiveness of the following high-temperature densification process, as the driving force for bulk diffusion is reduced. In this respect, high heating rates, allowing to reduce or skip the lower temperature processes entirely, increase the effectiveness of the densifying processes. This argument is particularly relevant when the starting powder is nanometric. Nanopowders, in fact, present an intrinsic higher sinterability, that might be lost in the presence of long, low-temperature annealing.

It has also been suggested that a higher heating rate might enhance densification through thermomigration or thermotransport effect, driven by the presence of macroscopic and microscopic temperature gradients generated when high heating rates are involved. The details of these phenomena are quite complex and strongly dependent on the thermo-electrical characteristics of the materials. We already discussed the macroscopic temperature gradients before. For conducting materials, the possibility of microscopic temperature gradients at the point of contact between the grains has often been suggested in the literature. A quantitative analysis of such a phenomenon, however, shows that it might become relevant only in the case of very large grains of materials presenting low thermal conductivity. When nano or submicrometric powders are involved, the build-up of temperature gradients within each grain is impossible, as the thermal conduction is too fast, even in the presence of large currents flowing between the grains.

Examples of Application

In the last three decades, SPS enjoyed a growing success as a method for the densification of functional and structural materials. There are countless examples of applications including almost any class of material. A comprehensive list of these applications can be found in the available reviews and in the extensive original literature (Grasso *et al.*, 2009; Guillon *et al.*, 2014; Orrù *et al.*, 2009). Most of these applications involve materials that can also be obtained using more conventional sintering techniques, but that benefit from the reduction in sintering times, in sintering temperatures, and grain growth offered by SPS. Materials that are traditionally considered harder to sinter received more attention. Among them, there are surely refractory metals, such as W, Ta, and Re, that present outstanding mechanical and thermal properties, but are difficult to densify completely due to their high melting point. The use of SPS allows, in this case, to reduce the maximum required temperature and sintering time, with a consequent reduction in contamination, from oxygen and graphite, and a reduction in the grain size. Similar results have been

obtained in the case of intermetallic phases for advanced high-temperature structural applications. Typical examples are represented by the intermetallic phases present in the Nb/Al and Ti/Al systems. In this case, reactive sintering has often been applied using SPS. In this approach, mixtures of the basic metals have been treated, performing synthesis and densification in the same process. SPS is generally quite effective in enhancing solid-state reactions kinetics, as the applied uniaxial pressure helps maintaining the ideal contact between the reacting phases. Smaller grain size has been obtained using this approach, with beneficial effects on the mechanical properties. Another typical area of application is represented by ultra-high-temperature ceramics, such as borides, carbides, and nitrides of Zr, Ti, and Hf. These materials, with their extreme thermal characteristics, have always represented a challenge for material processing. The interest towards them, on the other hand, has been growing significantly in the last two decades. Long sintering cycles using HP or HIP have always been the only viable approach for their densification. However, this approach produced significant grain growth and contamination, reducing the possibility of obtaining full densification. The use of SPS allowed reducing the processing time drastically, with an overall beneficial effect on the material properties and a significant reduction in the production costs. Another field where SPS attracted large interest is represented by transparent ceramics for optical applications. The possibility of obtaining transparent polycrystalline ceramics, characterized by lower costs and better mechanical properties than single crystals, has driven this interest. Many applications can be found in the literature, with particular emphasis on yttrium-aluminum-garnet (YAG), spinels, zirconia, and alumina. However, contamination from graphite and formation of crystallographic defects, mostly oxygen vacancies, deriving from the strongly reducing conditions typical of SPS, have been found to reduce the in-line transmission in most cases.

Besides these more conventional applications, SPS opened the possibility to realize materials that are problematic or even impossible to obtain using conventional sintering approaches. In the following sections we present a brief review of these applications.

Nanostructured Bulk Materials

The nanostructure has a profound influence on the physical and chemical properties of materials. For this reason, the possibility of obtaining bulk materials preserving the unique properties deriving from the nanostructure is considered particularly attractive. Bulk materials presenting a grain size between 10 and 50 nm present, in fact, superior mechanical properties and, in some cases, unique functional characteristics. The nanometric grain size can also alter the phase equilibria in polymorphic materials, allowing to stabilize materials in unusual crystallographic forms. Sintering and grain growth, however, share the same mechanisms and obtaining full densification without the loss of the nanostructure is a challenging feat. Conventional sintering approaches have largely failed in this respect. The introduction of SPS offered a valuable alternative, that proved to be particularly effective. Because of this, SPS has become the technique of choice for the production of bulk nanostructured materials. Fig. 6 shows how the use of short sintering times (5 min) and high uniaxial pressure allow reducing drastically the grain growth in the case of SPS sintering of nano-YSZ.

Functionally Graded Materials

FGM represents a class of materials characterized by a gradient in composition or microstructure along one direction. Although these materials have been introduced well before the SPS technology became available, the use of SPS opened new possibilities for their development, particularly regarding the materials presenting a gradient of microstructure. In early acceptance, FGMs were

Fig. 6 Relationship between the sintering temperature, applied pressure and final grain size in the case of nanometric fully-stabilized zirconia (8% Y₂O₃). Reproduced from Anselmi-Tamburini, U., Garay, J.E., Munir, Z.A., 2006. Fast low-temperature consolidation of bulk nanometric ceramic materials. *Scr. Mater.* 54, 823–828.

characterized only by the presence of compositional gradients. Typical examples were represented by materials presenting a gradual transition from metallic to ceramics (see Fig. 7). Even in the case of these conventional FGM, the SPS approach offers some advantages, as the shorter sintering times allow reducing the possibility of interdiffusion and chemical reaction between the individual components during the process. Obtaining FGM presenting a gradient in porosity or in grain size is much more difficult using conventional sintering methods. The realization of these materials, in fact, requires the presence of steep temperature gradients. The localized heat generation mechanism, typical of SPS, is in principle well suited for obtaining these conditions. It has been shown that significant temperature gradients can be obtained quite simply just modifying the assembly of the die or changing its shape, as shown in Fig. 8. A simple offset of the die body, leaving only one of the punches outside can produce strong axial temperature gradients, in the range of hundreds of degrees per cm. More complex temperature gradients can be obtained modifying the shape of the die. An example of an innovative material that can be obtained using this approach is shown in Fig. 9. Here a sample of B_4C presents an axial gradient of porosity that was then backfilled with molten aluminum under vacuum. This allowed realizing a material that is extremely hard and wear-resistant on one end and presenting a high toughness on the other. Radial instead that an axial gradient of porosity and composition can also be obtained. The proper control of the temperature gradients requires careful design of the die, which must be guided by appropriate numerical modeling.

Non-Equilibrium Materials

The short sintering times involved in the SPS technology offer the unique possibility to realize the densification of materials that are out of equilibrium. This is generally impossible to obtain with conventional sintering, as the long high-temperature treatments involved with these techniques drive necessarily the materials towards their most stable state. Over the last few years, a large number of densifications of non-equilibrium materials using SPS have been reported. A typical example, already mentioned before, is represented by nanometric materials. The intrinsic instability of most nanophases towards high-temperature treatment makes them impossible to densify using conventional sintering methods. Other non-equilibrium materials are represented by amorphous phases or glasses. A very interesting example of application in this area is represented by the densification of metallic glasses (**Fig. 10**). These materials are generally obtained by rapid solidification, an approach that limits strongly the possibility to produce objects with complex shapes and in bulk form. The possibility to densify powders deriving from gas atomization or by mechanical alloying opens new and interesting possibilities of application. Numerous examples have been reported (Choi *et al.*, 2007; Chu *et al.*, 2012). Another interesting application is represented by the possibility to produce bulk materials presenting an unstable or metastable crystallographic structure. Several examples have been reported, particularly in the case of metastable crystallographic forms stabilized by the nanostructure, as for undoped cubic/tetragonal zirconia and titania in anatase crystallographic form (Maglia *et al.*, 2010; Masahashi, 2007). The densification of supersaturated solid solutions represents another field of particular interest. The densification of Al alloys with a content of other metals above their saturation limit has been reported (Zhang *et al.*, 2013). Particularly interesting is the possibility to maintain local compositional gradients, in the micro or nanometric range, as it opens the possibility to realize materials with unique functional or transport properties not accessible to homogeneous materials. A typical example is represented by the densification of core-shell powders (Airimioaei *et al.*, 2017), avoiding the homogenization by interdiffusion. Recently the possibility to obtain doping localized at the grain boundary, taking advantage of the low-temperature surface diffusion has also been demonstrated. Other examples of technologically relevant metastable material are represented by the formation of non-equilibrium composites containing diamond or cubic boron nitride (Herrmann *et al.*, 2012).

Innovative Aspects and Future Evolutions

SPS technology has grown in the last two decades to become one of the most relevant innovations in sintering. However, the area of field-assisted sintering is still evolving, and in the last few years some new trends emerged, that might challenge the more 'conventional' applications. Some of these evolutions try to answer unresolved limitations of the technique; others are just attempting to expand its application limits. In the following sections, some of the most interesting new evolutions will be briefly described.

High and Ultra-High Pressures

As already noted before, the maximum uniaxial pressure achievable with a standard SPS tooling, made out of high-density graphite, falls in the range between 100 and 150 MPa. In the last few years, however, attempts to extend such limit has been

Fig. 10 SEM images of the specimens of $\text{Cu}_{46}\text{Zr}_{42}\text{Al}_7\text{Y}_5$ metallic glass sintered at 593K (a) and 653K (b); EDS spectra taken from the specimen sintered at 653K (c); high-resolution TEM micrograph taken from the specimen sintered at 653K (d); Bright-field TEM image of the specimen sintered at 653K (e) and the corresponding SAD patterns (f)–(h) taken from the indicated by “A”, “B” and “C” in (e), respectively. Reproduced from Chu, Z.H., Kato, H., Xie, G.Q., *et al.*, 2012. Consolidation and mechanical properties of $\text{Cu}_{46}\text{Zr}_{42}\text{Al}_7\text{Y}_5$ metallic glass by spark plasma sintering. *J. Non-Cryst. Solids* 358, 1263–1267.

reported several times. The possibility to use much higher pressure can be particularly beneficial for applications involving the densification of nanocrystalline materials. As reported in Fig. 6, the temperature required to obtain a certain level of densification decrease drastically with the increase of the uniaxial pressure. As a result, high-pressure densification is particularly beneficial when the grain growth must be controlled, as in the case of the densification of nanopowders. High or ultra-high pressure may also induce phase transformation in some solid materials.

To achieve uniaxial pressures in the range of the hundreds of MPa or even of few GPa, the typical SPS tooling must be properly modified. An example of a high-pressure setup is reported in Fig. 11 (Anselmi-Tamburini *et al.*, 2006). The external part of the die is very similar to a standard SPS tool and is made out of high-density graphite. This part is where most of the current flows and the heating takes place. The internal part of the die is where the sample is placed and the high pressure is realized. This part must be made with materials with the appropriate compressive strength, such as silicon carbide, tungsten carbide, or cemented carbide. This setup allows achieving 3–4 GPa on samples that are few mm in diameter. Although this pressure is still at least an order of magnitude below the limit achievable with diamond anvil systems, it is enough to observe some pressure-induced phase transformations. The highest temperature achievable is limited to 700–800°C when cemented carbides are used, but can be much higher in the case of silicon carbide or tungsten carbide tools.

Tooling Optimization

Despite a large number of successful applications, SPS is often considered a technique with limited applicability to large scale industrial processes. This conviction derives in part from few misconceptions developed in early applications, but is also based on some real issues that are limiting its scaling up. In this respect SPS presents two main limitations: there is a limit to the maximum size of the samples that can be produced and it allows to obtain only one sample at a time. Despite their relevance, little effort has been paid in trying to mitigate these two limitations. Both limitations are ultimately related to the tooling design. The maximum sample dimension is mostly controlled by two factors: (1) the maximum current that can be delivered by the power supplier used in SPS machines, and (2) the difficulty of maintaining a uniform temperature distribution in very large samples. Regarding the first point, it must be noted that current intensities above 40–50 kA are impractical for economic and logistic reasons. This threshold limits the maximum achievable sample dimension to disks of 30–40 cm in diameter, as the graphite tools used in SPS require very high current to produce enough joule heating to warm up large samples. In this respect, hot pressing and HIP can produce even larger samples with lower investment and operating costs. However, the geometry of large dies is never usually optimized, as it is generally obtained by a simple scaling up of dies used for the smaller samples. Recently it has been shown that a proper design of the tools can save considerable electric power through an optimization of the current fluxes (Giuntini *et al.*, 2016, 2015). A careful design of the tools, achieved through numerical modeling, also allows optimizing the temperature distribution in the case of large samples. An example of this approach is shown in Fig. 12, where the electrical cross-section of the punches has been properly reduced in order to obtain a substantial reduction in the electric power required to reach high temperatures and uniform temperature distribution within the sample.

Analogous considerations can be applied to the other limitation of SPS, represented by the possibility to produce only one sample for each sintering cycle. Also in this case, the limitation is mostly related to a lack of evolution in the tooling design. In fact, it is possible, at least in principle, to produce several samples with a single sintering cycle using an appropriate tool. In Fig. 13 few examples of possible setups are reported, presenting parallel, serial, or parallel-serial alignment of tool cavities. This approach, however, has received very limited attention in the SPS practice. Such complex tools, in fact, are difficult to make and to control, particularly in terms of temperature uniformity, as the current fluxes are in this case even more complex and difficult to predict without an accurate numerical modeling (Fig. 14).

Finally, it is worth mentioning the possibility of realizing objects characterized by complex shapes. Traditionally, SPS samples present a disk-like or cylindrical shape. Recently, however, it has been presented the possibility of realizing more complex shapes through near-*net*-shape approaches involving the use of the so-called “deformable interfaces” or “controllable interfaces” method (Manière *et al.*, 2019). In this approach, a layer of deformable material, usually a graphite foil, is shaped to define a complex geometry. The foil is then placed within a traditional SPS tool, and the two volumes separated by the foil are filled with similar or different powders. At the end of the SPS densification, the two regions can be easily separated, producing one or two complex shape elements.

Hybrid Heating

As mentioned before, one of the main challenges in SPS technology is represented by the possibility to control the temperature distribution during the sintering process; a problem that is particularly relevant in the case of very large samples. We have seen as a way to mitigate this problem lays in the optimization of the tool design through numerical modeling. Such an approach, however, is time-consuming and must be repeated every time a change in the sample size or geometry is required. A more general-purpose approach involves the use of a secondary heating source, allowing a more uniform temperature distribution. The use of a secondary heating element also allows mitigating the other factor affecting the scaling up of SPS, represented by the maximum power allowed by SPS power supplier. Machines allowing to use two heating methods at the same time are usually identified by

the term ‘hybrid SPS’ and have become commercially available in the last few years. Two different methods of secondary heating are generally used: conventional resistance furnace and induction heating. The first approach is less expensive, but it goes somehow in conflict with the most typical characteristic of SPS, represented by the possibility to use fast heating rates. In this respect induction heating is more congruent and received more attention. An example of the typical setup used in a hybrid SPS with induction heating is shown in Fig. 15. Despite their advantages, the use of a hybrid SPS is still very limited, in part due to the high cost of the apparatus, but appear very promising when scaling up towards very large sample dimensions is crucial for the application.

Introduction

Sintering is an essential step in the processing of ceramic, metallic materials and composites, under which particles are bonded to form a coherent solid structure with the help of heat and/or pressure. The oldest known man-made sintered ceramic specimen date from ~26.000 years before present (B.P.) in the upper Paleolithic period and were found in Dolni Věstonice, currently in Czech Republic. [Vandiver et al. \(1989\)](#) estimated that the oldest ceramics specimen were fabricated from local soils (loess) at a temperature range of 500–800°C and that the mechanism of sintering was impurity-initiated, most likely liquid phase sintering. The other specimen found helped to confirm that this processing method was further used in many parts of the world to fabricate different types of objects, such as fired clay water vessels in ancient Egypt ~10.000 years B.P., the first sintered metals specimen such as gold, bronze, copper, silver in the Middle East ~3.000 years B.P., the first porcelains in China ~1.600 years B.P. and gold-platinum alloy jewelry in Colombia and Ecuador 300 years B.P. ([German, 2013, 2014](#)).

Important milestones in sintering were achieved in the 20th century thanks to the rapidly growing electricity industry. We can take as examples the use of “electric spark sintering” patented by [Voelker \(1900\)](#) in 1900 to sinter refractory metals like tungsten, the highlight of sintering atmospheres by [Coolidge \(1913\)](#) during the investigations and development of sintered rods *via* direct current sintering and then drawing these down to form. These advances in the sintering of refractory metals led to the development of WC-Co composites dies, allowing significant technical advances on liquid phase sintering, and carbides for machinery obtained by hot pressing, invented by [Bridgman \(1933\)](#).

From ~1940, a surge in the production of sintering products in the automotive, electronics and medical sectors was observed, following World War II ([German, 2014; Danninger et al., 2017](#)). The first theoretical concepts on solid state sintering were proposed by [Frenkel \(1945\)](#) and [Kuczynski \(1949\)](#) the one for liquid phase sintering by [Lenel \(1948\)](#) and [Kingery \(1959\)](#). Coble later introduced the different stages of sintering as well as different mass transport mechanisms ([Coble, 1961a,b](#)). New multi-parametric methodologies to optimize physical properties, master microstructural evolution and costs of sintered materials, were rationalized by Ashby thanks to sintering maps ([Ashby, 1974; Ashby and Jones, 1996](#)). From the late 60's to date, new sintering techniques emerged. We can list microwave sintering, ([Voss, 1973](#)) selective laser sintering ([Deckard, 1989](#)) and those belonging in the category of Field Assisted Sintering Technology (FAST) taking advantage of fast firing to enhance densification (Flash Sintering, ([Cologna et al., 2010](#)) Spark Plasma Sintering (SPS), ([Inoue, 1966a,b,c](#)), etc...). Very recently, intensive efforts were focused on low-temperature sintering (<400°C) through the development of energy efficient and environmentally friendly processes. From a general point of view, major new opportunities were thus opened including the integration of inorganic materials with different structures, the processing of nanostructured ceramics, the co-sintering of ceramics, polymers or metals. The search for reducing the sintering temperature has also led to the emergence of new materials and composites in the field of multiferroics materials (Cool-SPS) ([Hérisson de Beauvoir et al., 2018](#)) and for microwave devices (Ultra Low Temperature Co-fired Ceramic (ULTCC)). Besides, the cold sintering process (CSP) and the hydrothermal sintering (HS- also called hydrothermal hot pressing), both based on the use of solvent and uniaxial pressure, have shown an impressive potential for the fabrication and the design of high performance ceramics at low temperature.

This chapter focuses on these two different low sintering temperature processes. Besides the cost- and energy-efficiency and low environmental impact, both these techniques are enabling the fabrication of ceramics and ceramics-based composites with advanced properties at low temperatures, while overcoming some technological barriers associated with high temperature processing methods, such as the sintering of metastable and low decomposition temperature materials as well as the co-sintering of multimaterials of a new kind. The main difference between these two techniques is that hydrothermal sintering operates in closed conditions whereas CSP operates in open conditions. Fundamental aspects of the two processes as well as illustrations of their potentialities in terms of materials are discussed and described. Then, through a comparative study based on ZnO, the complementarity of the two processes is emphasized. The current challenges and future outlook will end this chapter.

Design of Experimental Set Up

In both cold sintering and hydrothermal sintering, a liquid which acts as a solvent is introduced into powder and mixed *via* conventional powder processing techniques (*e.g.*, mortar and pestle, cryomilling, ball milling, *etc.*) or by a vapor transport process prior to sintering ([Fig. 1](#)). In the existing literature, it was shown that for both these processes, the liquid selection depends critically upon the materials to densify. The interaction between the liquid and the powder throughout all the steps of sintering is

Fig. 1 Description of different processing steps in HS and CSP. central to obtain high relative densities. In both CSP and HS, the mixture powder/liquid is externally and mechanically compressed either in a die (CSP) or in an autoclave (HS) over short periods of time. Each process requires a specific set up.

Hydrothermal Sintering

In the early 70's, Roy *et al.* (1972), Roy and Gouda (1973) prepared, at Penn State University, cement pastes with excellent mechanical properties and almost no porosity by hot pressing cementitious powders and water. In the mid-70's, further studies were made by Hirano and Sōmiya (1976) and Toraya *et al.* (1982) on reactive hydrothermal sintering to obtain densified oxides, starting from metal powders at temperatures higher than 900°C. In combining both these approaches, Yamasaki *et al.* (1986) from Kochi University developed an apparatus for “hydrothermal hot pressing”, based in uniaxial pressure of a mixture of powder and solvent in a system sealed with PTFE (Teflon™) gaskets. This technique was further developed and renamed “hydrothermal sintering” (or “solvothetmal sintering” when water is replaced by a non-aqueous solvent) by the group of Goglio at the University of Bordeaux (Ndayishimiye *et al.*, 2018a,b,c). The hydrothermal sintering operates in a closed system, which requires a specific design of the pistons to recover the solvent expelled during the densification in tanks designed for this purpose. Moreover, they have succeeded to reach higher experimental performances (higher temperatures and pressures) while keeping gaskets out of the hot zone and maintain the system hermetically sealed to control the hydrothermal equilibrium conditions under the sintering (Fig. 2) (Goglio *et al.*, 2018, 2019).

Cold Sintering

The cold sintering process operates in an open system, with non-equilibrium conditions (Guo *et al.*, 2019). The die used in the cold sintering process (center of Fig. 3) allows the evaporation of the solvent during the process. As shown in Fig. 3, many different materials systems and configurations such as ceramics (Funahashi *et al.*, 2016), metals, ceramic/ceramic composites (Guo *et al.*, 2018a,b,c), layered ceramic/metal composites (Guo *et al.*, 2017), layered ceramic/ceramic composites (Funahashi *et al.*, 2017), ceramic/polymer composites (Guo *et al.*, 2018a,b,c), layered ceramic/polymer composites (Funahashi *et al.*, 2017), and low temperature metallization (Hérisson de Beauvoir *et al.*, 2019) were demonstrated as a proof of concept under CSP.

Overview of Experimental Conditions

The experimental conditions implemented are given in Table 1.

Sintering Mechanisms

HS and CSP are both geologically-inspired processes as their operating conditions are based upon the use of a transient liquid, temperature and pressure (Table 1), which are close to what is observed in the earth's upper crust, about 10 km under our feet (Fig. 4). In this region of the earth, we can find several minerals such as limestone, quartz or gypsum, which densify under geochemical conditions over very long times. One of the major mechanisms that drives this densification is the pressure solution creep (or dissolution-precipitation creep), which is a three-step process: dissolution → mass transport → precipitation, occurring through chemical potential gradients induced by the presence a solvent and pressure. In both CSP and HS, most of the densification is driven by mechanical-chemical effects (pressure solution creep) in synergy with chemical effects.

Mechanical-Chemical Effects

The mechanical-chemical effects in CSP and HS are based on a pressure solution mechanism. This deformation mechanism takes place following chemical potential gradients from highly constrained areas ($\mu_{s,1}$) with enhanced dissolution and high chemical potential to low constrained areas at particle surfaces with a lower chemical potential ($\mu_{s,2}$), through the liquid film separating particles. The driving force of pressure solution ($\Delta\mu_{tot}$) is therefore defined as Eq. (1): (Gratier *et al.*, 2013)

$$\Delta\mu_{tot} = \mu_{s,1} - \mu_{s,2} \quad (1)$$

This process is divided into three main steps (Fig. 5(a)): dissolution at the contact points between particles, mass transport through the liquid film and precipitation at pore surfaces, whose driving forces are $\Delta\mu_D$ Eq. (2), $\Delta\mu_T$ Eq. (3), $\Delta\mu_P$ Eq. (4), respectively.

$$\Delta\mu_D = \mu_{s,1} - \mu_{l,1} \quad (2)$$

$$\Delta\mu_T = \mu_{l,1} - \mu_{l,2} \quad (3)$$

$$\Delta\mu_P = \mu_{l,2} - \mu_{s,2} \quad (4)$$

$\mu_{l,1}$ and $\mu_{l,2}$ represent the chemical potential of the solute-rich and the solute-poor liquid phase, respectively.

The pressure solution is a stress-driven mass transfer process that is conceptually similar to Coble and Nabarro-Herring creep laws which are driven by grain boundary and intragranular diffusion, respectively (Urai *et al.*, 1986; Gratier *et al.*, 2013). The main

Table 1 Experimental conditions implemented in CSP and HS

	CSP	HS
Sintering conditions	T: 25–350°C P: 0–700 MPa (uniaxial)	T: From boiling point of the solvent up to 500°C P: 0–350 MPa (uniaxial)
	Specific solvents: Molten hydroxides or salts, chelating agents and deep eutectic solvents	
	Time: Several minutes to few hours	
	Solvent: Aqueous and non-aqueous solvent (hydrothermal sintering becomes solvothermal sintering) solutions	
	The use of a co-solvent or a mineralizer is possible	
	Shrinkage monitoring <i>via in situ</i> dilatometry	

difference is that, due to the lower activation energy of diffusion in liquids than in solids or at grain boundaries, pressure solution (or solution-precipitation) creep occurs at lower temperature than these two other mechanisms (Fig. 5(b)).

Chemical Effects

The dynamic interaction of the liquid solvent and the surface of inorganic materials during HS or CSP is quite complex and very challenging to predict experimentally. The reactive force field (ReaxFF) molecular dynamics technique is suitable for theo-

Fig. 4 Superposition of terrestrial environments on the P-T diagram of water. The Earth's core, mantle, crust and atmosphere are shaded medium gray and are centered on the average geotherm (subsurface) and lapse rate (atmosphere). The ocean and crust geotherms are plotted separately and meet at $P = 2000$ bar, $T = 200^\circ\text{C}$, corresponding to a depth of ~ 10 km. (ARXIV <https://arxiv.org/abs/1005.2440>).

retical investigation of the chemical interactions between solvents and inorganic surfaces in cold sintering conditions (Sengul *et al.*, 2018a,b, 2019). Indeed, these interactions generally involve dynamic chelating reactions, dehydration and cluster formation whose understanding is critical to thoroughly investigate the *in situ* chemical effects in cold sintering. As an example, Fig. 6 shows the entire dynamic of the precipitation of Zn^{2+} ion from zinc acetate species on ZnO surfaces during the CSP of ZnO with an acetic acid solution. Fig. 6(a) shows acetate and water molecules prior to the decomposition reactions. Fig. 6(b) shows the deprotonation of methyl hydrogen by surface oxygen. Then, the water molecule dissociated into bridging hydroxyl and terminal hydroxyl (Fig. 6(c)), which is followed by a nucleophilic attack to methyl carbon, resulting in $\text{C}_2\text{H}_3\text{O}_3$ radical formation (Fig. 6(d)). Fig. 6(e) shows the dissociation of the $\text{C}_2\text{H}_3\text{O}_3$ radical, followed by its decomposition to carbon dioxide and formaldehyde (Fig. 6(f)).

Fig. 6 Snapshots from ReaxFF MD simulations showing the acetic acid decomposition to formaldehyde and carbon dioxide at different time frames: (a) 50 ps, (b) 100 ps, (c) 135 ps, (d) 150 ps, (e) 153 ps and (f) 165 ps. It is important to note that ReaxFF molecular dynamics technique can be used to simulate chemical effects in hydrothermal sintering as well (Ndayishimiye *et al.*, 2019).

The influence of chemical effects in HS and CSP can also be investigated by *post mortem* classic structural or microstructural analysis techniques on as-obtained densified materials such as X-ray diffraction (XRD), thermogravimetric analysis (TGA), X-ray photoelectron spectrometry (XPS), scanning electron microscopy (SEM) or transmission electron microscopy (TEM) coupled with energy dispersive X-ray spectroscopy (EDS), Fourier transform Infrared spectroscopy (FTIR), nuclear magnetic resonance (NMR) or time-of-flight–secondary ion mass spectrometry (TOF-SIMS). The use of several of these complementary characterization techniques is often necessary to understand complex chemical phenomena.

In the case of hydrothermal sintering of amorphous silica, the nature of chemical effects and their evolution depending on the initial amount of water in the sample have been studied using FTIR and solid state NMR (^1H MAS NMR and ^1H) ^{29}Si CP-MAS NMR) (Ndayishimiye *et al.*, 2018a,b,c). Goglio *et al.* have shown that, during sintering, native silanol groups (both internal and at the surfaces) polycondensate to induce the *in situ* chemisorbed water release, form siloxane Si-O-Si bridges in particular between touching particles and then initiate the creation of sintering necks (Fig. 7). The initial surface functionalization favors these chemical effects which favor the densification synergistically with the mechanical-chemical ones. In this way, it has been shown that physisorbed water may act as solvent released *in situ* and may be sufficient to activate the dissolution-precipitation mechanisms.

Different Pathways Towards Densification Under Solvent-Assisted Sintering Processes

Different pathways towards densification can be considered with cold sintering (and hydrothermal sintering) as shown in Fig. 8, which illustrates the basic steps and feasible strategies for various material systems based upon their dissolution nature. Guo *et al.* (2019) indicated that these steps depend on the materials, solvents and processing parameters considered. The “material” parameters determined by chemical and structural characteristics are the chemical composition, crystal structure, particle size and particle size distribution and surface functionalization. As previously stated, it is obvious that solvent selection is critical in HS (or solvothermal process in the case of non-aqueous solvent) and CSP. Both aqueous and non-aqueous solvents can be used, enabling chemical reactions with the powder under the carefully chosen processing conditions (heating and cooling ramps, temperature, pressure, pressure profile, time). They must exhibit a good affinity with the powder (wetting ability and solubility) and must ensure efficient mass transport in HS and CSP systems.

Three different routes are possible upon the dissolution nature in HS and CSP systems:

- In the case of congruent dissolution, HS or CSP are straightforward as the material dissolves into the solvent with a homogeneous chemical stoichiometry, then the supersaturated solution precipitates to contribute to crystal growth. [Guo *et al.* \(2019\)](#) have also shown that solute gelation and the precipitation of an amorphous phase at grain boundaries can be observed in CSP if the evaporation is rapid. **Fig. 9** shows an example of an amorphous grain boundary observed after CSP of $\text{Na}_2\text{Mo}_2\text{O}_7$ ceramics. However, sharp grain boundaries are observed in the vast majority of the material.
- In the case of incongruent dissolution, ions with higher dissolution kinetics are leached. As a consequence, particle surfaces become passive, which separate the solvent and the crystalline phase, potentially hindering the densification. One of the strategies used to overcome incongruent dissolution is the use of a solvent saturated containing ions with the same nature of the leached ones. But there are systems like $\text{Li}_{1.5}\text{Al}_{0.5}\text{Ge}_{1.5}\text{P}_3\text{O}_{12}$ (LAGP), for which densification still occurs under cold sintering even when the incongruent dissolution of Li^+ and PO_4 does occur ([Berbano *et al.*, 2017](#)). As such, there must be additional interactions between surface structures and solvent species, allowing chemical effects with potentially many events to occur during cold sintering. The amorphous or secondary phases present at grain boundaries following this incongruent dissolution under cold sintering can be deleterious to properties, such as limiting ionic or electronic conduction ([Guo *et al.*, 2018a,b,c, 2019](#)) and, in the case of high-permittivity dielectrics, additional contribution of low permittivity interfacial regions ([Guo *et al.*, 2016a,b,c](#)).

The Role of Solvents

Illustration in the case of hydrothermal and solvothermal sintering of amorphous SiO_2

Goglio *et al.* designed a study to understand the role of physisorbed/chemisorbed/added water in hydrothermal sintering of amorphous silica. Naturally hydrated (5 wt% H_2O), partially dehydrated (3.4 wt% H_2O) and almost-fully dehydrated SiO_2 nanopowders (1.1 wt% H_2O) were used as starting materials. In the first two powders, water is present in the form of chemisorbed and physisorbed water while in the last case only physisorbed water is observed. From these nanopowders, pellets were obtained after hydrothermal sintering without the addition of solvent at 300°C , 190 MPa and 90 min. Another ceramic was obtained in the same temperature, pressure and time conditions starting with the naturally hydrated powder mixed with added water (42 wt% of added H_2O). The microstructures of these ceramics are presented in **Fig. 10**.

The microstructure significantly evolves with the hydration rate of the starting powder. Starting from the poorest hydrated powder (**Fig. 10(a)**), a compact with a homogeneous microstructure consisting in an array of closed-packed silica nanoparticles is obtained. In this sample, no densification is observed. When the initial water amount in the starting powder increases, a remarkable close packing of particles, partially embedded into an amorphous silicic phase is observed (**Fig. 10(b)**). This starting water amount, even quite low, favors the cohesion of the assembly as it is sufficient to initiate dissolution-precipitation promoted by the presence of physisorbed water which acts as the solvent, mainly in the most constrained areas in the material. When the powder is the most naturally hydrated, a highly dense microstructure with residual pores is observed all over the sample, alongside with some few areas with vermicular-type microstructure; which confirms that the sintering has been efficiently promoted by the presence of chemisorbed water (enhancement of chemical effects) and physisorbed water (mass transport is favored during mechanical-chemical process) (**Fig. 10(c)**). When water is added in a large amount, a significant increase in densification and a drastic microstructural change are observed (**Fig. 10(d)**). Indeed, the absence of reminiscence of both the initial morphology and organization of nanoparticles attests to an effective densification of the powder. In the case of spherical SiO_2 , an excess of water indeed disturbs the natural self-organization of nanoparticles and the observed removal of the excess water generates some local

Copyright 2019 Elsevier.

turbulences that induce major stacking faults. It appears then necessary to define the best experimental conditions to find a compromise between the progress of densification and the water release.

One solution may consist in the promotion of dissolution for a given solvent amount. In this way, mineralizers can be added. In the case of silica, it is well known that the silica dissolution is enhanced by a pH increase. As a consequence, relative density increases up to 86% when 0.2 M NaOH (20 wt% of solvent in the system) is added under 300°C and 350 MPa (Fig. 10(f)). In such a case, all the mesopores (10 vol%) that were observed when solvent was pure water (Fig. 10(g)) totally disappear, due their filling by precipitation after a promoted dissolution step. Moreover, if the NaOH concentration is ten times higher under the same pressure and temperature conditions, a 98% dense ceramic consisting in pure-quartz is obtained (Fig. 10(e)) with a remarkable epitaxial growth at the grain boundaries. In this case, the use of a mineralizer in aqueous solution allows to control the crystallographic nature of the precipitated phase (Ndayishimiye *et al.*, 2018c).

Another solution to regulate the dissolution and precipitation steps is to use a co-solvent or a non aqueous solvent (solvothermal process). For example, the less polar nature of ethanol relative to water makes the silica dissolution lower, thus favoring the precipitation near the zone of dissolution and leading to a slower propagation of the densification and to a slower release of the water. Moreover, ethanol is more compressible than water which favors its transport into the matrix (Goglio *et al.*, 2019). Consequently, the use of ethanol as a co-solvent favors a fine control of the microstructure through a change from macroporous matrix in the case of pure water to mesoporous one with a pore size all the lower as the proportion of ethanol is high. When the sintering is performed at 300°C under 350 MPa during 90 min with 20 wt% of solvent, the relative density reaches 88% with mesoporosity in

quinary	Li _{1.5} Al _{0.5} Ge _{1.5} (PO ₄) ₃ , Li _{0.5x} Bi _{1-0.5x} Mo _x V _{1-x} O ₄

the case of a mix made of 75 vol% ethanol – 25 vol% water (**Fig. 10(h)**), while it equals to 84% with dominant macroporosity in the case of pure water (**Fig. 10(g)**).

As a conclusion it is obvious that the nature (aqueous/non aqueous, with/without mineralizer) and the amount of solvent in the case of hydrothermal sintering are a key point to achieve the densification while finely control the microstructure.

Illustration in the case of CSP

Besides, the emergence of cold sintering allowed to demonstrate the possibility to use other types of aqueous organic acid solutions (acetic acid, citric acid, ...), ketone, ester solvents or mixtures with boiling points below 200°C. Very recently, other very reactive solvents such as molten hydroxides or molten salts were used to densify high performance BaTiO₃ (Tsuji *et al.*, 2020) (**Fig. 11**), CeO₂, (Na_{0.5}K_{0.5})NbO₃, SrTiO₃, Na₃Zr₂Si₂PO₁₂ and many other polycrystalline ceramics in a single step at temperatures of 400°C or lower.

Sintering of Ceramics and Composites

Cold Sintering

More than 50 material systems, including quaternary and quinary compounds were successfully densified by the cold sintering process (**Table 2**). Among the inorganic materials that have been densified using cold sintering are microwave dielectrics with (Väätäjä *et al.*, 2017; Faouri *et al.*, 2019) or without magnetic phases (Guo *et al.*, 2017; Induja and Sebastian, 2018; Faouri *et al.*, 2019), ferroelectrics (Guo *et al.*, 2016a,b), piezoelectrics (Wang *et al.*, 2018), Li-ion cathodes (Seo *et al.*, 2017) and Li-/Na-ion electrolytes (Borbano *et al.*, 2017; Gustavo *et al.*, 2019; Lee *et al.*, 2019), semiconductors (Guo *et al.*, 2017; Gonzalez-Julian *et al.*, 2018), ceramic adhesives (Chen *et al.*, 2017) and refractories (Guo, *et al.*, 2017).

It is of interest to develop composite materials that possess better properties than the individual components. One of the major breakthroughs in cold sintering is that the technique enabled the fabrication of ceramic-polymer composites with a high volume fraction of ceramics (up to 99.9%), that were initially impossible to obtain, due to temperature gaps between elevated temperatures conventionally necessary to sinter ceramics and decomposition temperatures of polymers (Guo *et al.*, 2016c, 2018c). The other types of ceramic-based composites are with 2D materials, carbon nanofillers and metals, with amounts generally about 5 vol% or less. These new materials exhibit modified/enhanced electrical, mechanical and/or thermal properties, and are most importantly sintered at low temperatures.

The fabrication of new and usual dense composites composed of ceramics, polymers and metals is now possible. This construction, called “polycermet”, is still yet to be explored as it opens the door for new possibilities in Materials Science.

Hydrothermal Sintering

The hydrothermal sintering (or hydrothermal hot pressing) was used previously by Japanese groups for the densification of several oxides (either porous or compact) such as SiO_2 , TiO_2 , hydroxyapatite, CaCO_3 , $\text{Ca}_3\text{Co}_4\text{O}_9$, zeolites, ZrO_2 , $\text{Na}_x\text{Co}_2\text{O}_4$, $\text{Sn}_{1.24}\text{Ti}_{1.94}\text{O}_{3.66}(\text{OH})_{1.50}\text{F}_{1.42}$, (Yamasaki *et al.*, 1990; Yanagisawa *et al.*, 1990; Yamasaki *et al.*, 1992; Katsuyama *et al.*, 2007; Xie *et al.*, 2009) with relative densities ranging between 30% and 80%, and up to 99% in some cases (Nishizawa *et al.*, 1984; Katsuyama *et al.*, 2006; Li and Hashida, 2007). Other studies highlighted that hydrothermal sintering might be suitable for the treatment of industrial or nuclear wastes. (Yanagisawa *et al.*, 1989).

Recently, Goglio *et al.* have shown that in addition to an accurate control of the thermodynamic parameters (related to temperature and pressure), the surface functionalization and crystallinity of the starting powder, as well as the nature of the solvent are powerful chemical levers to easily achieve relative densities ranging from 98% to 100%. They can be applied to oxides with the possibility of matching the crystalline nature of the phase in the final ceramic (Ndayishimiye *et al.*, 2018c, 2019).

One of the challenges is to perform the sintering of complex assemblies with materials that exhibit differences in their chemical and physical characteristics. The bonding of hydroxyapatite on titanium metals or magnesium alloys with no specific surface treatment of the metals/ alloys, developed by Onoki *et al.* (2005, 2009, 2011), was the first type of also multimaterials developed by hydrothermal sintering. More recently, Goglio *et al.* developed a manufacturing strategy based, on the one hand, on grain boundary engineering to design 0–3 type $\text{La}_{0.66}\text{Sr}_{0.34}\text{MnO}_3/\text{SiO}_2$ nanocomposites hydrothermally sintered starting from core@shell nanoparticles, discriminating inert from reactive interfaces during the densification (Ndayishimiye *et al.*, 2018a; Kaman *et al.*, 2019). The enhanced reactivity at the liquid/solid interfaces in hydrothermal (or solvothermal) conditions should appear as an interesting lever to design specific multimaterial assemblies.

Comparison Between Cold Sintering and Hydrothermal Sintering: Case Study on ZnO

To investigate the similarities and differences between HS and CSP, ZnO has been chosen as a case study: a ZnO powder has been sintered with aqueous 2 M acetic acid solution at 155°C and 320 MPa with different holding times, the experimental protocol implemented in both processes being the same (Ndayishimiye *et al.*, 2019). All as-obtained ceramics consist in highly densified wurtzite zinc oxide.

At first glance, both processes show close values of relative density (systematically $\geq 97\%$) and analogous evolutionary trends. The relative density first decreases with time probably due to a pore growth induced by pore migration along with boundary migration and then increases, which may indicate a near-similar mechanical-chemical contributions, governed by the pressure solution creep.

However some slight differences between both processes exist underlining the influence of the open/closed system specificity (Fig. 12). First, the stabilization of zinc acetate bridges is highlighted in HS samples by SEM and XRD characterizations. ReaxFF molecular dynamics simulations have been conducted for the theoretical investigation of the chemical interactions between solvents and inorganic surfaces. Indeed, these interactions generally involve dynamic chelating reactions, dehydration and cluster formation whose understanding is critical to thoroughly investigate the chemical effects during sintering. In the case of CSP the solvent is considered in a gaseous state while it is kept liquid in the case of HS. The dissociation of water and acetic acid at the surface of particles leads to the formation of an hydroxide layer, tightly bounded to a solvent layer. The simulations show that CSP and HS mainly differ due to a distinctive chemical activity in the system: (1) in the case of CSP, the evaporation of the solvent induces the removal of the solvent layer, making the surface accessible to Zn^{2+} for precipitation, the process being highly governed by surface kinetics; (2) in the case of HS, the closed conditions make the tightly bounded solvent layer hydrothermally active as expected for such specific conditions which favors the formation of connected metal-organic complexes (zinc atom connected by acetate molecules); these chains then evolve towards clusters and are further converted into zinc-acetate crystals in longer timescale, which is consistent with a process governed by thermodynamics. Another difference between CSP and HS relies upon the grain size evolution over time (Ndayishimiye *et al.*, 2019). In both cases the grain sizes increases with holding time but if it is in a first stage higher in HS, it becomes higher in CSP for longer holding times. This can be explained by the fact that the dissolution is promoted in hydrothermal conditions favoring initial higher grain sizes in HS; however at longer times, the solvent remains in higher amount in HS than in CSP (evaporation) which makes more difficult to reach supersaturation and precipitation in HS; on the same time, evaporation considerable favors the supersaturation, hence the grain size increases significantly in the case of CSP. The different grain size evolution observed between both processes may also originate from the presence of oxygen vacancies, grain boundary thickness, grain surface roughness and the presence of residual acetates at grain boundaries.

The nature either closed (HS) or open (CSP) of the system influences the balance between thermodynamics and kinetics, hence the predominance of the elementary steps involved in the sintering pathway. In this way, solubility, dissolution/mass transport/precipitation kinetics, surface reactivity, pore shrinkage, water release, achievable densification, for example, will be dependent on the chosen process.

By their specificities, Cold Sintering and Hydrothermal Sintering represent complimentary low temperature sintering methods that cover an extremely wide range of experimental conditions from thermodynamic to strongly off-equilibrium conditions (Table 3). As a result, investigations conducted using these two processes undoubtedly enable deeper understanding of sintering mechanisms and versatile densification capabilities in terms of chemical compositions and nature of the target (multi)materials.

By taking advantage of this complementarity and flexibility, unique opportunities are opening for the design of microstructures combining ceramics, metals and/or polymers. Areas of applications that could not previously be exploited due to sintering conditions constraints are now accessible *via* simple to implement, inexpensive and energy-efficient processes.

Similarities	Sintering mechanism	Solvent-assisted sintering enabled by dissolution-precipitation process with possible synergistic chemical effects	
	Materials	Ceramics, ceramic-based composites, metals	

Current Challenges and Future Outlook

From a general point of view, the introduction of such solvent assisted sintering processes opens many major new opportunities in terms of material processing while ensuring cost saving, energy efficient and sustainable manufacturing process with a lower CO_2 emission, as illustrated in Section “Socio-Economic and Environmental Impact”. In addition, the sintering of thermodynamically unstable materials and the co-sintering of organic/inorganic composites has become possible thanks to the use of cheap and green solvents associated with a strong reduction of sintering temperature. However, to fully exploit the aforementioned potentialities offered by the Cold Sintering and the Hydrothermal Sintering, some key milestones, which are outlines below, still need to be completed.

Socio-Economic and Environmental Impact

Ibn-Mohammed *et al.* (2019) made a techno-economic analysis of several sintering techniques, such as hot pressing, conventional sintering, spark plasma sintering, flash sintering, microwave sintering, liquid phase sintering and cold sintering. In the study, the Sterling Pounds per ton of CO_2 saved ($\text{£}/\text{t}_{\text{CO}_2\text{-eq}}$) was used to evaluate the cost- and energy- efficiency in the manufacturing of three functional oxides: ZnO, PZT and BaTiO_3 . This figure of merit links the initial capital investment with

Fig. 13 Ranking of cost-effectiveness of sintering techniques for (a) ZnO, (b) PZT and (c) BaTiO₃ ceramics. Reprint from Ibn-mohammed, T., Randall, C.A., Mustapha, K.B., *et al.*, 2019. Decarbonizing ceramic manufacturing: A techno-economic analysis of energy efficient sintering technologies in the functional materials sector. *Journal of the European Ceramic Society* 39 (16), 5213–5235. doi:10.1016/j.jeurceramsoc.2019.08.011. energy savings, within a framework derived from ranking principles such as marginal abatement cost curves and Pareto optimization.

It was estimated that for the three functional oxides, CSP was the most economically attractive sintering option, indicating lower capital cost and best return on investment as well as considerable energy and emission savings (Fig. 13).

The authors of the study reminded that even though the viability of CSP was established as a competitive and sustainable alternative to other sintering techniques, its transition from laboratory to industry will require hugely different facilities and instrumentation as well as relevant property/performance validation to fully validate its potential.

Modeling for a Better Understanding of the Involved Mechanisms

One of the main challenges in CSP and HS is to provide a detailed fundamental understanding of the mechanisms required not only to be able to extend these processes to a wider range of materials but also to control more accurately the microstructure, in particular in terms of grain size. One of the leads towards a better fundamental understanding of the mechanical-chemical effects in CSP and HS is to evaluate and adapt the already-rich geochemistry/geophysics work on the pressure solution creep to “experimental” and laboratory-scale systems. In terms of chemical effects, several ReaxFF molecular dynamics simulations have been experimentally validated. The investigated systems helped to raise the awareness on the high importance of a deep understanding of the solvent-particle interface chemistry in confined spaces, as well as the complexity of the cascade of chemical reactions taking place in these areas during sintering processes. Several unpublished observations let us assume that a better knowledge of chemical species/complexes obtained during the dissolution step may be key to perfect some of the theoretical models, as well as understand the implications they have on the mass transport step as well as on the kinetics of precipitation, which may lead to a certain extend on grain growth. It is clear that all this information may help to shape a comprehensive roadmap for solvent selection in HS and CSP, the development of new types of functional ceramic-polymer, ceramic-metal or polycermet composites; multiscale modeling approaches are also essential to reach in-depth insights on sintering mechanisms and

control the microstructures. The different mass transport pathways and reactions, which are all interrelated, must be clearly specified in order to identify the limiting mechanisms and then densification kinetics. The confrontation between experiments and modeling at different scales is essential here. These aspects are currently addressed as part of the “Hydlic” project (2018) funded by the French National Research Agency (ANR-18-CE08-0006).

Aging of As-Sintered Ceramics

The two processes aim to produce ceramics dedicated to a very wide range of applications. Whether considering applications in the field of electronics or biomedical, the issue of reliability, durability and recyclability of ceramics will be essential. Lifetime and aging of ceramics performed at low temperature must be tested to prove the competitiveness of the processes. In the case of HS, it has been discussed to the presence of residual water confined into pores may induce a further surface modification as a rehydration, hence contributing to the aging of the material. In addition, one microstructural feature that is inherently affected by the sintering process is the grain boundaries. Defect chemistry at the grain boundaries will prevail the quality of ceramics and to a large extent the structural and functional properties. Their in-depth characterization is thus mandatory.

In a very fast-moving industry, introducing new materials and/or processes asks for a new assessment of life cycle whose different steps must be considered to ensure the reliability and safety of future products.

Increase of the TRL (Technological Readiness Level): From Laboratory to Factory

The early focus on driving the TRL has been in the form of strategic demonstrations of different materials and showing property performances in the form of monolithic and complex multilayer functional devices. So; currently the work is at a TRL 1–3 to 4 stages, with companies confirming the early data. It is obvious that the transition from laboratory to factory is also a major challenge, and identify the appropriate applications to drive the transition is under discussion. Technological specifications mainly related to the pressure will have to be considered, as the ceramic industry preferably uses relatively low pressures. Although it is noteworthy that in the powder metallurgy industry the warm pressing forming stage uses equipment that operates above 500 MPa. It was recently observed that the homogeneity of densification will be an essential parameter to control, especially for larger sintered components. The control of a pressure applied homogeneously as well as the kinetically-controlled solvent elimination during sintering can be major factors that can guarantee success under CSP. Even at the laboratory level samples above areal dimensions of $7 \times 7 \text{ cm}^2$ have been reported. In the same way, the design of both production equipment and experimental procedure will have to be adapted to the sintering of components with complex shapes, as it has been demonstrated in the case of the SPS (Manière *et al.*, 2017). Additive manufacturing of dies and punches offer interesting opportunities in this regard. Furthermore, the development of continuous processes on a certain number of products is an exciting perspective for both these low temperature sintering techniques.

Microwave Sintering of Ceramics

Jean-Marc Chaix, Université Grenoble Alpes, French National Centre for Scientific Research, SIMaP lab, Grenoble, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

Microwave sintering refers to techniques that use microwaves for heating and sintering powder beds or compacts, in particular ceramic powders. It has given rise to an increasing number of scientific papers since 1995, with a specific development in China in the last 15 years (Fig. 1).

All these techniques use the interaction (*coupling*) between the electromagnetic field and materials for producing heat. The coupling material can be the powder compact to be sintered or specific coupling parts (*susceptors*) which capture the microwave energy then heat the compact by classical heat transfer (conduction, convection, radiation). This heat production inside the oven, limited to the processed parts and susceptors, differs from the classic heating by the hot walls, which requires heating large volumes, so that microwave heating is expected to enable higher heating rates and reduced energy consumption. Beyond these economical positive aspects, the high heating rates open the possibility to get improved materials with finer microstructure, and the interaction of microwave with the ceramic powder is expected to enhance sintering phenomena, opening ways for processing materials at lower temperatures. The bulk internal heating should also help getting a better temperature homogeneity. These potential advantages have been extensively listed and partly discussed in various review papers (Katz, 1992; Oghbaei and Mirzaee, 2010; Bhattacharya and Basak, 2016).

However, sintering ceramics requires high temperature (over 1200°C), and ceramists willing to use microwaves meet a major problem: the ability of ceramics to couple with microwaves is low at room temperature and may drastically increase at high temperature. It is uneasy to heat ceramics at low temperature, while they exhibit a tendency to show thermal runaway and hot spots at high temperature. Controlling temperature and heating homogeneity is also far from being easy, as the parts to be sintered, as well as thermal insulators, can strongly modify the field distribution inside the oven and its evolution with temperature during the process. The interpretation of experimental data therefore requires very careful and hard observations, so that a number of results from literature should be handled with care... and criticism!

For these reasons, microwave sintering is a very attractive technique for processing ceramics, but requires understanding the major aspects of electromagnetic fields and interactions inside microwave ovens dedicated to sintering ceramics, from both physical and technological points of view. The purpose of the present chapter is to provide the reader with knowledge and information for a fruitful use of microwaves in sintering ceramics.

Microwaves and Dielectric Heating

The information presented in this section and the following one is simplified and limited to aspects that appear necessary for understanding what is involved in microwave sintering of ceramics. The reader wishing to have more complete details should read basic physics books or books dedicated to microwave engineering (Owyang, 1989; Pozar, 2012).

Propagation of Electromagnetic Fields

Microwaves are electromagnetic waves with frequencies f in the range [300 MHz, 300 GHz], *i.e.*, between the FM radio and the infrared radiations. In an infinite medium, two orthogonal electric E and magnetic B fields constitute electromagnetic waves (Fig. 2) which propagate in direction z defined by the wave vector k according to:

$$\left. \begin{aligned} E &= E_0 \sin(2\pi ft - kz) \\ B &= B_0 \sin(2\pi ft - kz) \end{aligned} \right\} \quad (1)$$

In vacuum or air, the wave moves at the speed of light c , so that $k = \frac{2\pi f}{c}$. The corresponding wavelength $\lambda = \frac{c}{f}$ is in the range [1 mm, 1 m].

Microwaves are mainly used for telecommunication applications, and only a few wavelengths are available for heating in domestic and industrial application, the most common ones being 2.45 GHz ($\lambda = 12.25$ cm) 915 MHz ($\lambda = 32.79$ cm) but higher frequencies around 30 ($\lambda = 1$ cm) or 60 GHz ($\lambda = 0.5$ cm) are also used (Katz, 1992).

Electromagnetic fields obey the Maxwell's equations. In the case of sinusoidal fields, E and B fields can be written using complex numbers $X = X_0 \exp(j\omega t)g(x)$, where $j = \sqrt{-1}$, $\omega = \frac{f}{2\pi}$ the angular frequency and $g(x)$ the space distribution, so that Maxwell's equations in an homogeneous medium write:

$$\left. \begin{aligned} \nabla \cdot E &= 0 & \nabla \cdot H &= 0 \\ \nabla \times E &= -j\mu_0\mu_r\omega H & \nabla \times H &= -j\omega\varepsilon_0\varepsilon_{er}E \end{aligned} \right\} \quad (2)$$

in which ε_0 and μ_0 are the dielectric permittivity and magnetic permeability of vacuum ($\varepsilon_0\mu_0 = c^2$). In the case of ceramic materials,

Fig. 1 Number of paper published with a title containing 'microwave' and 'sintering'. Source: Web of Science.

Fig. 2 Propagation wave vector k , electric (E) and magnetic (B) fields of electromagnetic waves in an infinite medium (plane wave, transverse electromagnetic TEM) and in a waveguide with transverse electric (TE) and transverse magnetic (TM) modes.

the relative magnetic permeability μ_r is almost equal to unity, so that the major characteristic of the material-microwave interaction is the effective relative permittivity ϵ_{er} , a complex value which accounts for dielectric interactions and electrical conductivity

$$\epsilon_{er} = \epsilon' - j\left(\epsilon'' + \frac{\sigma}{\omega}\right) = \epsilon' - j\epsilon_e'' \quad (3)$$

The real part of the permittivity ϵ' is always ≥ 1 ; the imaginary part ϵ'' accounts for the dipolar response. Both of them depend on the frequency, while $\frac{\sigma}{\omega}$ accounts for the contribution of the electrical conductivity σ . The effective imaginary part $\epsilon_e'' = \epsilon'' + \frac{\sigma}{\omega}$ is the practical parameter that governs the absorption of electromagnetic energy by dielectric heating in ceramics (see below section "Microwave Heating of Ceramics").

A major consequence of Eqs. (2) and (3) is that both E and H fields must be zero in perfect metals with infinite electrical conductivity ($\sigma = \infty$).

Dielectric Heating

Dielectric heating is the result of physical interaction between the electric field E and the material. It is the main microwave heating phenomenon in ceramic materials, so that the description will be limited here to the electric field effect. The effect of the magnetic field component can be significant in metals (El Khaled *et al.*, 2018), in particular Fe, Ni and Co and ferromagnetic materials (Mishra and Sharma, 2016), for which significant heating results from interactions with the magnetic field B . When a field of amplitude E ($E = \sqrt{2}E_{RMS}$) and frequency f is present in the material, the power dissipated per unit volume of the material is:

$$P = 2\pi f \epsilon_0 \frac{\epsilon_e'' E^2}{2} = 2\pi f \epsilon_0 \frac{\epsilon' \tan \delta_e E^2}{2} \quad (4)$$

The ratio $\tan \delta_e = \frac{\epsilon_e''}{\epsilon'}$ is the *loss tangent*. It is often used for characterizing the ability of a material to be heated by microwave energy dissipation and available in literature. Some techniques for measuring the dielectric properties of materials are calibrated for measuring $\tan \delta_e$ values. A material can be characterized either by the pair $(\epsilon', \epsilon_e'')$ or by the pair $(\epsilon', \tan \delta_e)$. Some authors call ϵ' the *dielectric constant* and ϵ_e'' the *loss factor*.

The physical origin of this energy dissipation is twofold: on one hand, the dielectric polarization effects associated to dipoles and charge carriers interaction with the oscillating field (ϵ'' in Eq. (3)), on the other hand the electric conduction ($\frac{\sigma}{\omega}$ in Eq. (3)).

Fig. 3 Reflection and transmission of a plane wave at the surface of a material: (a) transparent material; (b) absorbing material; (c) reflecting (opaque) material.

Fig. 4 Penetration depth in an absorbing material: (a) definitions in an infinite medium; (b) typical situations for different finite widths $w = 10 d$ (b1), $w = 2 d$ (b2) and $w = 0.1 d$ (b3).

These interactions have been detailed in reference books and review papers (Mishra and Sharma, 2016; Sun *et al.*, 2016). It is to be noticed that ε'' intrinsically depends on the wave frequency f , while $\frac{\sigma}{\omega}$ of course varies as $\frac{1}{f}$, so that, in practice, the dissipated power is not proportional to frequency f as Eq. (4) suggests.

Penetration Depth

Eq. (4) requires that the electric field is present inside the material. An important issue is therefore the penetration of the field into the material. When a wave in vacuum or air meets the interface with a material, part of it is reflected (Fig. 3). This reflection depends on the incidence angle and on the complex dielectric permittivity ε_e (Fresnel equations). In the case of normal incidence, the transmitted electric field relative intensity is typically:

$$\frac{E_t}{E_{ti}} = \frac{2}{1 + \sqrt{\varepsilon_e'}} \text{ when } \varepsilon_e'' \ll \varepsilon_e' \quad \frac{E_t}{E_i} = \frac{2}{\sqrt{2\varepsilon_e''}} \text{ when } \varepsilon_e'' \gg \varepsilon_e'. \quad (5)$$

Materials are often classified in 3 categories (Fig. 3):

- (1) transparent materials, in which the transmitted wave is not absorbed. This situation is observed when $\varepsilon_e'' = 0$. A significant part of the field is nevertheless reflected at the surface.
- (2) absorbing materials, in which the transmitted field is damped, due to heat dissipation, when ε_e'' is nonzero. Such materials can therefore be microwave heated.
- (3) Opaque materials, in which the electric field does not enter. "Fully reflective" would be a more convenient term. This is in particular the case in highly conductive metals, in which the imaginary part of the permittivity can be written $\varepsilon_e'' = \frac{\sigma}{\omega}$ with $\sigma \rightarrow \infty$, and the transmitted field is almost 0.

In absorbing materials, the energy absorption (Eq. (4)) leads to an exponential decrease of the field intensity as the wave goes on (Fig. 4(a)): $E = E(0)e^{-x/d_E}$. The characteristic length d_E is the penetration depth of the field, while $d = \frac{d_E}{2}$ is the penetration depth of the wave energy ($W \propto E^2 = E^2(0)e^{-2x/d_E}$). At these distances, the field (resp. energy) is decreased by a factor of $e = 2.718$ (Fig. 4(a)). These characteristic lengths depend on the dielectric properties as:

$$d = \frac{d_E}{2} = \frac{1}{2} \frac{c}{2\pi f} \frac{\sqrt{2}}{\sqrt{\varepsilon_e'^2 + \varepsilon_e''^2 - \varepsilon_e'}} = \frac{\lambda}{2\pi\sqrt{2}} \frac{1}{\sqrt{\varepsilon_e'^2 + \varepsilon_e''^2 - \varepsilon_e'}} \quad (6)$$

As expected from Eq. (4), the penetration depth in infinite when $\varepsilon_e'' = 0$, as no energy dissipation occurs, and decreases when ε_e'' increases. It is zero in perfect conductors ($\sigma = \infty$, $\varepsilon_e'' = \infty$). Calculated typical values for metals are a few micrometers around $f = 1$ GHz, Eq. (6).

Penetration depths enable to analyze the behavior of materials by considering a part with a finite width w (Fig. 4(b)). If d is small with respect to the material with (Fig. 4(b1)), field and energy will be absorbed in a thin layer: in such cases, the power dissipation is mainly located close to the surface. If d is large with respect to the material size (Fig. 4(b3)), heating is homogeneously distributed in the bulk, but only a limited amount of the wave energy is absorbed, which means that the heating may be

Fig. 5 Electric field distribution in the cross section of a waveguide in TE_{10} and TE_{20} modes.

poorly efficient. In the intermediate case, the absorption is optimal and distributed in the bulk, but might be poorly homogeneous in the bulk. Indeed, Fig. 4 is a simplified view, as a fraction of the emerging wave is also reflected back inside the materials when it reaches the second side, so that the situation when the penetration depth is not very small with respect to the sample size is more complex.

Waveguides and Applicators

A microwave furnace is generally constituted by a microwave generator, a waveguide, and the cavity in which the parts to be heated are placed, also called *applicator*.

Waveguide

In microwave processing of materials, the waveguide is generally a rectangular channel with metal walls, with cross section $a \times b$, with $b < a$ (Fig. 2). Due to reflections on the metallic walls, i.e., to boundary conditions which require the tangent components of E and B to be zero at the walls (assumed to be perfect conductors with infinite electrical conductivity), the electric and magnetic fields cannot be simultaneously orthogonal to the propagation direction z (Transverse Electric magnetic, TE) (Fig. 2(b)). Two main propagation ways are of practical interest, the so-called *Transverse Electric* (TE) and *Transverse Magnetic* (TM) modes (Fig. 2) in which either E or B is orthogonal to the propagation direction, the direction of second field being oscillating in the orthogonal plane (Chakravorty, 2014; Pozar, 2012). The TE mode presented here is generally more adapted to ceramics and dielectric heating, but results for TM mode are quite similar (Owyang, 1989). In the TE propagation mode, the solution of Maxwell's equations evidences that only a discrete series of propagation eigenmodes TE_{mn} exist, each of them defined by two integer numbers m and n . The E field amplitude in a cross section depends on the position (x, y) :

$$\left. \begin{aligned} E_x &= B_0 \frac{\lambda_c^2 f}{2\mu_0 b} \cos \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \\ E_y &= B_0 \frac{\lambda_c^2 f}{2\mu_0 a} \sin \frac{m\pi x}{a} \cos \frac{n\pi y}{b} \\ E_z &= 0 \end{aligned} \right\} \quad (7)$$

While the amplitude of the z component of the magnetic field is

$$B_z = B_0 \cos \frac{m\pi x}{a} \cos \frac{n\pi y}{b} \quad (8)$$

Those relations show that m is the number of half-periods of the fields along the x -axis, n the number along the y one (see example on Fig. 5). The critical value λ_c is to the maximum value of the wavelength λ above which the waves cannot propagate in the waveguide, associated to a minimum frequency $f_c = \frac{c}{\lambda_c}$.

$$\lambda_c = \frac{2}{\sqrt{\left(\frac{m}{a}\right)^2 + \left(\frac{n}{b}\right)^2}} \quad (9)$$

In this case, the effective wavelength is not the free wavelength λ of plane waves, but the *guided wavelength* λ_g associated to the considered mode:

$$\lambda_g = \frac{\lambda}{\sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \quad (10)$$

Fig. 6 Schematic view of a waveguide and single mode cavity in the case of propagation mode TE_{10} . (a) waveguide ended by a metal wall, forward wave (red), backward wave reflected by the wall (blue), and resulting standing wave (black) at arbitrary times t (dashed) and $t + dt$ (solid) with $dt \ll 1/f$; (b) single mode cavity, with a partially open wall (iris) which partially reflects the backward wave, and a mobile wall (plunger) which enables adjusting the cavity length L . The amplitude of the standing wave along the guide or cavity is shown below the guide.

Fig. 7 Computed electric field intensity in empty cavities: (a) a single mode cavity with TE_{105} mode in a WR340 standard waveguide (orthogonal cross sections along the propagation axis); (b) example of cubic multimode cavity (3 arbitrary orthogonal sections).

The lowest frequency and largest wavelength are when $m = 1$ and $n = 0$, $\lambda_c = 2a$ (Eq. (9)). In TE_{m0} modes (Eq. (7)), the electric field is parallel to the y -axis (Fig. 5). The so-called fundamental mode, TE_{10} has a single maximum along x in the center part of the waveguide cross section and provides the widest high field area.

Waveguides have to be adapted to the microwave frequency. Standards for waveguides, mapping the microwave range of wavelengths, have been defined for many years (Harvey, 1955). Several families of standards coexist (Brady, 1965). In the WR (Waveguides Rectangular) standard, the number refers to the size $a = 2b$ in 0.254 mm (0.01 in.) units. The WR340 ($a = 2b = 8.636$ mm) and WR975 ($a = 2b = 24.765$ mm) waveguides are commonly used for 2.45 GHz and for 915 MHz, respectively.

Tunable Single Mode Cavity

A single mode cavity is based on a waveguide bounded by a metallic wall at its end (*plunger*, *bypass*, *short*) and by a partially open wall (*iris*) on the generator side.

When a waveguide is ended by a metallic wall (Fig. 6(a)), the forward wave is reflected on the wall and gives rise to a backward wave, which is so that sum of fields is zero on the metallic wall. The superposition of the forward and backward waves results in a standing wave with the wavelength λ_g , and in a distribution of nodes and antinodes at distance $\frac{\lambda_g}{2}$ from each other.

A single mode cavity is obtained by adding an *iris*, i.e., a partly open wall, or an equivalent device, which roughly acts as a semi-transparent mirror (Fig. 6(b)), in a way that enables the cavity length to be adjusted (in many cases using a mobile bypass plunger to end the cavity). The multiple reflections between the iris and the plunger lead to a set of stationary waves inside the cavity. The amplitude of this standing wave reaches maximum values when the resonance condition is satisfied, i.e., when the length L of the cavity is tuned to $\frac{p\lambda_g}{2}$, where p is an integer number. The resonance mode is then denoted TE_{mnp} (TE_{105} on Figs. 6(b) and 7). When the length L departs from $\frac{p\lambda_g}{2}$, the distance between nodes departs from $\frac{\lambda_g}{2}$, and the amplitude of the electric field decreases. In such cavities, the parts to be heated are generally positioned at places where the electric field is maximal (antinodes).

Fig. 8 Schematic 2D and 3D cross sections a magnetron. The trajectories of electrons emitted by the heated cathode are curved by the magnetic field B_0 of a permanent magnet; their interaction with the cavities induces an oscillatory resonant electromagnetic phenomenon. The oscillatory electromagnetic field is collected by a side antenna and transmitted via a coaxial line.

Homogeneous heating can therefore be expected only for parts with a size significantly smaller than $\frac{\lambda_g}{2}$, typically 2–4 cm at $f = 2.45$ GHz or 5–10 cm at $f = 915$ MHz in a TE_{10p} , for WR340 and WR975 standards, respectively. In a real heating experiment, part of the power is dissipated in the cavity, so that, in the waveguide, the forward wave has a larger amplitude than the backwards one, resulting in the superposition of a progressive wave and a standing one.

Multimode Cavity

Multimode cavities are cylinders or parallelepipeds with much larger dimensions than the wavelength (Fig. 7). As the waves are no longer guided, multiple reflections on the cavity walls lead to a complex set of standing waves, which result from the combination of many different propagation modes. The typical length scale between nodes is of the order of $\frac{\lambda}{2}$, but with a very irregular and almost unpredictable distribution of intensities, including significant variations of the average amplitude inside the cavity (Fig. 7(b)). Two main techniques are used to counterbalance the field inhomogeneity: (1) rotating stirring blades, which generate varying wave reflections and periodically change the field space distribution; (2) rotating plates as sample supports. In both cases, the time averaged field seen by the part is more homogeneous, but actual heating homogeneity is far from being guaranteed. Using high frequencies (e.g., 30 GHz, $\lambda/2 = 5$ mm) leads to a large number of nodes/antinodes inside parts: this can be viewed as a way for ensuring better heating homogeneity (Bykov *et al.*, 2004).

These cavities have fixed dimensions, so that there is no possibility for tuning any resonance, but they can contain large parts or many parts at the same time: they are therefore considered more suitable for industry applications in most cases.

Microwave Generators

Magnetrons are the most common microwave power sources, which have enabled the development of microwave use since the years 1980 (Atuonwu and Tassou, 2018; Brittain, 1985; Thostenson and Chou, 1999). A magnetron is a vacuum tube device involving a central anode and a surrounding cathode holed by a series of open cavities, placed in a permanent magnet. The electromagnetic wave is produced by the motion of electrons in the inter electrode vacuum, the holes playing the role of resonant cavities (Fig. 8). The frequency of the emitted wave is defined by the dimensions and distribution of these cavities. Magnetrons are considered to have a high power conversion efficiency (70%–90%). They are the most commonly used devices at 915 MHz and 2.45 GHz. These cheap, robust and reliable devices produce polarized waves, with delivered powers from 500 W to several kW. The limitations are the polychromatic character of the emitted wave (a few MHz bandwidth at 2.45 GHz), the impossibility to control the phase of the wave, and the frequency shift when the delivered power is varied, which may be detrimental to the resonance adaptation in single mode cavities.

Gyrotrons (Bykov *et al.*, 2004) and travelling wave tubes (Thostenson and Chou, 1999) are also based on field emission by electrons, but in a quite different way. In gyrotrons, an electron gun produces an electron beam, and then a high magnetic field (superconducting magnet) induces helicoidal trajectories and radial field emission at cyclotron resonance. These devices are very large and much more complex than magnetrons, but produce a coherent monochromatic radiation at controlled frequency between typically 20 and 200 GHz. High powers ranging from some kW to 1 MW are possible. Gyrotrons applications include nuclear fusion research experiments and industry for heating applications.

Solid state microwave generators based on electronic transistors have emerged in the last past years as cost-effective alternatives to magnetrons for domestic and industrial applications (Atuonwu and Tassou, 2018). Such systems appear versatile and promising for heating applications. They enable a tunable microwave frequency with a very narrow bandwidth, independently of the power control.

Temperature Control in MW Heating

In conventional heating, the furnace temperature is transferred to the sample by classic heat transfer mechanisms (conduction, convection, radiation). Input energy is transformed into heat by the furnace, so that the temperature control is performed by adjusting the input power to balance the power required to heat the samples and walls and heat losses of the furnace and parts to be heated, which monotonously depend on temperature.

In a microwave furnace, the cavity is not heated: only the sample and its local surroundings (susceptor, thermal insulators: see next sections) are heated by the microwaves. We will call this the *load* of the cavity. The load itself must be considered as an active part of the heating system. Fig. 6 shows in the case of a resonant single mode empty cavity that part of the waves is reflected through the iris. This reflected part exists as well in loaded single or multimode cavities, and depend of the geometric and dielectric characteristics of the load. In a resonant cavity, the load changes the resonance conditions with respect to an empty cavity. Let us consider a cavity in which the length is adjusted to resonance with the load. The field will therefore be maximal and the dissipated power ($P \propto \epsilon'' E^2$) high, with a probably low reflected power. If the increase of temperature changes the dielectric properties of the load, which is generally the case, two very different consequences can be observed. If E is not too much changed, the increase of ϵ'' will increase P , causing a further increase of ϵ'' , and so on, leading to possible thermal runaway (see below section “Direct Heating, Inverted Gradient, Thermal Runaway”). The opposite result can be observed with even smaller dielectric property changes: the change in dielectric properties of the load tends to make the cavity out of resonance, so that the electric field drops down. In this case, the field and the absorbed power decrease while the reflected power increases, so that a higher input power is required, with the cost of a drop in power efficiency. This simple example shows that the temperature control by only adjusting the input power may have dramatic consequences on the efficiency. In practice, whatever the type of cavity, it can even lead to quite inefficient heating. The characteristics of the cavity must therefore be adjusted together with the input power, through the cavity length in the case on single mode cavities or by devices placed along the waveguide between the generator. This is also-called impedance matching and tuning, as the microwave furnace can be seen as an electric circuit or transmission line (Owyang, 1989; Pozar, 2012). The high temperatures required for sintering ceramics makes this phenomenon an important issue.

The present chapter does not aim at giving details on the technical aspects of temperature control, but the reader can find in literature some examples of possible strategies (Croquesel *et al.*, 2015; Marinel *et al.*, 2018). Anyway, it is important to understand and keep in mind that technical difficulties exist and explain that, in a number of papers dealing with microwave sintering, the temperature cycle is not accurately controlled.

Microwave Heating of Ceramics

Dielectric Properties of Ceramics

In ceramics, the real part ϵ' of the permittivity slowly increases with temperature (Figs. 9(a) and 10(a)). On the contrary, the imaginary part ϵ'' may in some cases exhibit a strong increase, which tends to be exponential-like, while other materials have a limited evolution.

The strong increase is often associated to the thermal activation of conduction phenomena, which make the term $\frac{\sigma}{\omega}$ in Eq. (3) increase drastically. It is for instance the case in zirconia (Figs. 9(b) and 10(b)), known as a ionic conductor at high temperature:

Fig. 10 Examples of dielectric properties and penetration depth of different ceramics and glasses at 2.45 MHz: quartz, Duran ceramic-glass, alumina and 3Y zirconia: (a) Permittivity real part ϵ' ; (b) Permittivity imaginary part ϵ'' ; (c) Penetration depth d . Adapted from Li, E., Nie, Z., Guo, G., Zhang, Q., 2009. Broadband measurements of dielectric properties of low-loss materials at high temperatures using circular cavity method. *Prog. Electromagn. Res.* 92, 103–120. Wu, L., Zhang, Y., Wang, F., *et al.*, 2019. An On-Line System for High Temperature Dielectric Property Measurement of Microwave-Assisted Sintering Materials. *Materials* 12, 665. doi:10.3390/ma12040665. Batt, J., Binner, J., Cross, T.E., *et al.*, 1995. A parallel measurement program in high temperature dielectric property measurements: An update. In: *Microwaves: Theory and Application in Materials Processing III*, Ceramics Transactions. American Ceramic Society. pp. 243–250.

several authors (Greenacre, 1996; Wroe and Rowley, 1996) found that conductivity was predominant at high temperature and proposed relationships including an activation energy Q : $\epsilon''_e = \frac{\sigma}{\omega} = A \exp(-Q/RT)$. In spite of a relatively low coupling at room temperature, microwaves can heat these good coupling materials, but the strong evolution of ϵ''_e with temperature makes the temperature control difficult (see below). Materials such as some ceramic glasses (Fig. 10) or silicon carbide (SiC) have an intermediate value of ϵ''_e which moderately evolves with temperature.

Materials such as pure alumina show a significant increase in ϵ''_e (Fig. 10), but the value of ϵ''_e remains small below 500 or 1000°C: these low coupling (*low-loss*) materials are therefore quite uneasy to heat from room temperature. Quartz is a remarkable example of quasi-transparent material, with a low (<5) and almost constant real part ϵ' , and a very small value of the imaginary part ϵ''_e , which remains far below 10^{-2} at 1500°C (Fig. 10). This makes quartz a good material for sample supports and thermal insulator parts, although its mechanical properties quickly drop down above 1000°C.

It is necessary to point out that these dielectric properties are very sensitive to the structure and composition of the material, including contamination and doping, porosity in the case of powder and sintered materials, and to microstructure. The large difference between the two authors' values in 3Y-zirconia on Fig. 9 is probably due to the use of different materials. The smaller but significant difference between the two "Batt" curves, obtained on dense parts from the same provider come from the measurements made in two different labs, in the background of a comparison program (Batt *et al.*, 1995). Techniques for measuring complex dielectric permittivity are based on the microwave response of a cavity when a sample is placed inside it (or at a boundary) and on the analysis of this response using a model (Li *et al.*, 2009; Murthy, 1994; Volkovskaya *et al.*, 2018; Wu *et al.*, 2019). These measurements are sensitive to the sample density, size, shape and surface state, and even more difficult in the case of high temperature measurements. In this context, data from literature must be considered as mainly indicative.

Direct Heating, Inverted Gradient, Thermal Runaway

Direct heating is when the parts to be heated (and for instance sintered) are placed in the cavity and heated by the field. In this situation, as the cavity walls are cold and the heat produced in the bulk of the part, an inverted gradient is expected with respect to classical furnaces. Unlike in classical furnaces, where gradients are transient and occur during heating, the inverted gradient can be stable even during an isothermal stage, as heat is continuously produced in the bulk and removed at the surface. Indirect proofs of such situations can be observed on Fig. 11: the coarse microstructure in the center of the microwave sintered alumina evidences a large overheating, while the microstructure close to the surface is similar to the one of the homogeneous part sintered using the same thermal cycle in a conventional furnace.

Because of the permittivity evolution, penetration depths decrease when temperature increases (Fig. 10). The expected bulk heating is often effective when the width of sintered parts is below 1 or 2 cm, which is the case of most ceramic parts, as penetration depths generally remain above 1 cm (Fig. 10) in most ceramics. However, in the case of ceramics such as zirconia, with a strong loss factor increase and the need for reaching high temperatures during sintering, the penetration depth can become millimetric, leading heat production to be localized close to the surface.

A more dramatic issue associated to the strong variation of the dielectric permittivity imaginary part in high coupling (high loss) materials is the thermal runaway: an increase of temperature generates an increase in ϵ''_e , which in turn (Eq. (4)) generates a

Fig. 11 Compared microstructures of Al_2O_3 –40vol% ZrO_2 mixed powders samples sintered at 1500°C by conventional and microwave heating observed on axial cross sections, at the center and close to the top surface. Temperature is measured by thermocouple close to the sample the conventional furnace, and by calibrated IR camera in the (single mode) microwave cavity. Fig. 12 Hot spot observed by IR camera during direct heating of a 3Y-TZP 8 mm cylinder. The temperature difference between the blue points and the average surface of the sample is about 400°C. The dotted black line marks the limit of the top surface of the sample. Picture by T. Garnault, Univ. Grenoble Alpes.

temperature increase... When it occurs at the whole part scale, this thermal instability induces an increase in the heating rate, leading to a hardly uncontrollable temperature increase.

A less controllable effect is the appearance of *hot spots*, when the non-uniform electric field or some composition/density variations in the material induce a local over-temperature, amplified by the runaway. Such hot spots during a sintering process can induce local over densification or melting, as well as thermomechanical gradient leading to fractures. In most cases, anyway, the user will try to avoid or limit the effects of thermal runaway, in particular temperature gradients. Thermal runaway and hot spots are tempered by heat diffusion phenomena: they are therefore limited by low heating rates/power but in turn limit the high heating rates that can be practically reached with safe samples.

Indirect and Hybrid Heating With Susceptors

A common solution to both heating low loss materials and improving thermal homogeneity of highly temperature sensitive medium- or high-loss ones is to introduce intermediate parts, called *susceptors*, in the cavity. These parts made of medium- or high coupling materials with low temperature sensitivity catch the electromagnetic field power then transmit heat to the material of interest by classic heat transfer mechanisms (conduction, convection and mainly radiation at high temperature) and limit the field seen by the material. A classic material is silicon carbide (SiC), in the form of dense parts or powders (Fig. 12).

The nature, geometry and position of susceptors determines the heating efficiency, but also the electromagnetic field around and inside the parts (Fig. 13). A fully closed susceptor acts as a field barrier, leading to *indirect heating* of the material. An open

Fig. 13 Simulation of the electric field of a low coupling material ($\epsilon' = 5$, $\epsilon'' = 0.05$) in direct heating and two cases of hybrid heating: 4 rods (picket fence) and tube susceptors (typically SiC $\epsilon' = 40$, $\epsilon'' = 3$). The sample is centered on an antinode of electric field of a single mode TE_{10n} 2.45 GHz cavity.

susceptor allows the material to be partly heated by the field. In this *hybrid heating*, the materials benefit from some aspects of bulk heating (inverted gradient) and from potential specific effects of the field-materials interactions (*e.g.*, sintering enhancement). Using a closed configuration to have a lower field is a way for limiting hot spots and improving homogeneity in high temperature sensitive materials such as zirconia. An open configuration will promote an assisted heating at low temperature and maximize the direct part of heating in a low-loss material such as alumina. Various strategies have been developed for optimizing susceptor configurations with respect to the properties of materials to be processed (Bhattacharya and Basak, 2016).

Thermal Insulators and Casketing

The high temperature of samples and susceptors while the cavity walls are kept close to room temperature requires the use of thermal insulators, and refractory supports. These materials must be as transparent as possible to microwaves at room and at high temperature. The large amount of air in highly porous granular or fibrous thermal insulators is a favorable factor, but materials with intrinsic low absorption of microwave (large penetration depth) are necessary. Typical convenient materials are aluminosilicate fibers, cordierite, quartz, yttria, boron nitride BN, silicon nitride Si₃N₄ (Bhattacharya and Basak, 2016; Evans *et al.*, 1999). The upper limit temperature, the thermal efficiency and the absorption widely differs from one material to another. Efficient thermal insulation is obtained by placing the sample and susceptors inside closed caskets (Fig. 14), which can be constituted by several layers of insulating materials (Bhattacharya and Basak, 2016; Holcombe and Dykes, 1990).

Although the absorption of these materials is low, their volume can be much larger than the sample, so that, in the case of direct heating of low-loss materials, the insulator package can absorb a major part of microwave radiation and act as a susceptor. This effect could be enough for initiating the heating of materials such as alumina, which exhibits a very low coupling at room temperature and a significant increase of its loss factor when temperature is increased.

Microwave Sintering of Ceramics

A Successful Way for Sintering Almost All Ceramics

A great variety of ceramics have been successfully sintered using microwaves over the past 30 years: structural ceramics (Al₂O₃, ZnO, SiC, MgAl₂O₄, Y-PSZ, Y-TZP/Al₂O₃, TiO₂), bioceramics (hydroxyapatite), functional ceramics (ZnO, BaTiO₃), composites (MgO-Y₂O₃, ZrB₂-B₄C, WC-Co), magnetic ceramics (Ni-Zn ferrites), translucent or transparent ceramics (AlN, MgO, ALON)... Details can be found in various review papers (Das *et al.*, 2009; Karayannis, 2016; Katz, 1992; Oghbaei and Mirzaee, 2010). Experiments involve a high diversity of frequencies (from 915 MHz to 50 GHz and above), of cavities (single mode, multimode, rectangular or cylindrical), using direct, hybrid or indirect heating.

Beyond the very effective possibility to save time and energy by heating directly a volume (sample and susceptors if any) smaller than the entire oven in conventional heating, several specific advantages were studied or observed, which are discussed in the following sections.

Fig. 14 Examples of sintering caskets used in a 2.45 GHz single mode cavity with 8 mm cylinders powder compacts: (a) porous material insulating box and (black) SiC cylinder susceptor (configuration of Fig. 13(d)); (b) fibrous insulator cylinder for direct heating; (c) insulating casket constituted by an inner and an outer cylinders separated by air for optimizing field absorption (the casket cap has been removed). The sample is marked in yellow in (b) and (c) and is inside the SiC box in (a).

Fig. 15 Example of results showing densification by microwave sintering (full lines) at much lower temperatures than in conventional furnaces (dotted lines) for different powders: Al_2O_3 -0.1 wt%MgO, Al_2O_3 65% γ /35% α , Al_2O_3 -40 vol.% ZrO_2 . Densification Enhancement and Lowered Sintering Temperature

Many papers, in particular in early works on microwave sintering, have shown surprising results, with high densification obtained at temperatures far below the temperature required in conventional furnaces (Fig. 15), with shorter dwell times. The temperature shifts between densification curves reach 100–400°C. This must however be considered carefully. A first point is that some papers compared results obtained with different and maybe uncontrolled heating rates, significantly higher in microwave heating than in conventional heating. The use of high heating rates to minimize non-densifying sintering mechanisms such as surface diffusion and promote densifying mechanisms such as GB or bulk diffusion, which generally show higher activation energies, is a classic strategy for improving densification (and minimizing grain size). This phenomenon could explain, at least partly, some observations when microwave heating is fast. A second explanation, which applies even in case of identical heating rates, is the misvaluation of temperature in microwave experiments.

Sample temperature evaluation during microwave heating is a fundamental issue. Placing thermocouples inside samples can induce strong effects due to perturbations or concentration of the electric field as well as measurement bias due to heat conduction by the metallic thermocouple or microwave heating of the thermocouple itself (Pert *et al.*, 2004). Recent works (Santos *et al.*, 2019) showed in the case of porcelain that temperature was underestimated 50°C when thermocouples were used, with respect to calibrated pyrometers and PTCRs (process temperature control rings), as thermocouples measure temperature apart from the sample. The authors estimated that the sintering temperature reduction by microwaves for porcelain sintering was therefore not

Fig. 16 Compared densification (dilatometric) curves of alumina compacts using conventional and (direct) microwave heating (single mode) at 25°C/min. (a) γ -alumina; (b) α -alumina, with evidence of the $\gamma \rightarrow \alpha$ phase transition. After Croquesel, J., 2015. Etude des spécificités du frittage par micro-ondes de poudres d'alumine alpha et gamma (PhD). Grenoble-Alpes, Grenoble. Croquesel, J., Bouvard, D., Chaix, J.-M., Carry, C.P., Saunier, S., 2015. Development of an instrumented and automated single mode cavity for ceramic microwave sintering: Application to an alpha pure alumina powder. *Mater. Des.* 88, 98–105. doi:10.1016/j.matdes.2015.08.122.

verified. Radiation based devices (optical pyrometers, IR cameras) are therefore preferred. They read temperature directly on the sample surface. As the sample emissivity (or emissivity ratio in two-color pyrometers) is sensitive to the material composition, density and surface roughness, calibration is a key point for valuable measurements. Around 1200°C, using an emissivity of 1 or 0.9 when the actual sample emissivity is 0.75 typically leads to temperature underestimations of 75 and 50°C, respectively; these underestimations increase with temperature. In early papers, these aspects were either ignored or not clearly mentioned, but as time goes on, works on microwave sintering give increasing attention to correct temperature calibration.

Another source of temperature underestimation is the above-mentioned inverted temperature gradient in microwave heating: the surface temperature evaluated by pyrometers can be much lower than the bulk temperature. The results for Al_2O_3 -40 wt% ZrO_2 on Figs. 11 and 15 are from the same experiments: the grain size difference observed on Fig. 11 between the center and the top of the sample, where temperature was measured, clearly agrees between the 110°C shift observed on Fig. 15.

The addition of these effects makes that a number of conclusions about the large decrease of the sintering temperature associated to microwave heating should be revisited. This does not mean that this microwave effect is not real, but it is probably less systematic and of lower magnitude than announced in many cases.

An important point to consider is whether this lower temperature densification is effective until full density. In some systems (Fig. 16(a)), the densification of compacts starts at lower temperature, but slows down when the sample density is above 90%, so that full density is not reached at lower temperature than in conventional sintering.

A variant of the observation of lowered densification temperature in microwave sintering is that the activation energy evaluated from densification curves is lower than in conventional heating. Apparent activation energy Q is a useful tool for comparing densification curves, a practical concept that enables to handle a simple form of the relationship between the densification rate and temperature. It is based on the assumption that the effects of temperature T and density ρ can be separated: typically $d\rho/dt = f(\rho)\exp(-Q/RT)$. This is characteristic of thermally activated mechanisms, and Q is frequently associated to a thermally activated dominant (rate limiting) mechanism for interpreting the results. In this background, the apparent decrease of the apparent activation energy of densification during microwaves heating is a practical way for characterizing the effect of microwaves. Interpretations in terms of mechanisms would be hazardous. Biased temperature measurements of course induce biased calculations of activation energy.

Finer Microstructures

The possibility to obtain smaller grain size by microwave sintering is often pointed out as an expectation related to either the high heating rate or specific field-material interactions (microwave effects). Independently of the heating technique, high heating rates and ultrafast firing are considered as ways to get fine microstructures and interesting properties (Ji *et al.*, 2017). Recent works (Bykov *et al.*, 2016) suggest that an efficient control of the microwave input power could take advantage of the thermal runaway phenomenon, which is similar to the so-called *flash sintering* by Joule heating, driven by the thermal runaway due to thermally activated conductivity (Dancer, 2016).

Fig. 17 Sintering trajectories in a pure alumina powder, using conventional and microwave heating modes. Data from Croquesel, J., Bouvard, D., Chaix, J.-M., Carry, C.P., Saunier, S., 2015. Development of an instrumented and automated single mode cavity for ceramic microwave sintering: Application to an alpha pure alumina powder. *Mater. Des.* 88, 98–105. doi:10.1016/j.matdes.2015.08.122. Zuo, F., Saunier, S., Marinel, S., *et al.*, 2015. Investigation of the mechanism(s) controlling microwave sintering of α -alumina: influence of the powder parameters on the grain growth, thermodynamics and densification kinetics. *J. Eur. Ceram. Soc.* 35, 959–970. doi:10.1016/j.jeurceramsoc.2014.10.025.

Regarding microwave effects on microstructure, very different results were obtained. Some papers indicate smaller grain sizes using microwaves; other papers observe higher grain sizes, consistent with higher bulk temperatures. Enhanced coarsening would be compatible with specific microwave effects as such effects can also enhance grain growth. Some results indicate smaller grain size in microwave sintering. It is however important to keep in mind that comparing two microstructures with almost the same density is often irrelevant, as the experimental correlations between density and grain size clearly show a drastic increase when density is above 98%. Fig. 17 shows an example in which a large number of experiments in a wide range of final densities have shown that the size *vs.* density curve strongly varies above 98% density and is the same for conventional and microwave sintering. Obtaining high density, even using microwaves, requires final stages at high temperatures. During this final stage, density evolves much slowly than in earlier stages, and grain growth can take place, and is even enhanced if the first densification step was short and kept a high driving force for grain growth.

Non-thermal Effects

The words *non-thermal effects* refer to effects of microwaves that cannot be attributed to the heat dissipation of the electromagnetic energy, through the thermal activation of diffusion in sintering mechanisms. Non-thermal effects consequently result from specific direct interactions, and their consequences are changes in the evolution (densification, grain growth...) with respect to observations at the same temperature when no electromagnetic field is present. The densification enhancement at low temperature presented in the previous section is an example. Another example is the effect on phase transitions (Fig. 16(b)) (Croquesel *et al.*, 2016; Rybakov *et al.*, 2008).

The *ponderomotive force* in microwave assisted materials processing was introduced to account for microwave effects on plasticity and sintering (Rybakov *et al.*, 2012; Rybakov and Semenov, 1994). It is based on the observation that the motion of charged vacancies is influenced by the instantaneous electric field E . An additional driving force must therefore be considered and added to the concentration gradient ∇C in the vacancy diffusion flux J :

$$J = D \left(-\nabla C + C \frac{q}{kT} E \right) \quad (11)$$

As E symmetrically oscillates as $\sin(2\pi ft)$, its time average over a time period is expected to be 0 and to have no average effect. However, in regions close to interfaces with high field and charge concentration gradients, the promoters of this theory calculated that the time average $\langle C \frac{q}{kT} E \rangle$ is nonzero. This induces vacancy fluxes at interfaces and surfaces, which modify the mass balance. Theoretical calculations and computer modelling were used to analyze the resulting effect on surfaces and around the grain-grain-pore triple lines. They led to the conclusions that the effect depends on the orientation of the field with respect to the surface or grain boundary, and can induce mass flow which contribute to densification. It was calculated that the associated driving force is proportional to E^2 and may in some cases be significant when compared to classic driving forces (Booske *et al.*, 1998; Rybakov *et al.*, 2013). As these effects require triple lines, they are expected to be more effective in the first steps of sintering than in the final stage. This is in agreement with some observations, as for instance the early densification under microwave which seems to be slowed down when high densities are reached, as observed in the case of α -alumina (Fig. 16(a)). Unfortunately, no macroscopic formulation that could be included in sintering models is available for introducing ponderomotive force effects in usable densification models.

Other theoretical works have shown that, due to so-called *micro-focusing effects*, the electric field can be strongly amplified at particle contacts due to local sharp shapes (Birnbom *et al.*, 1998; Li *et al.*, 2015) and that the local field is favorably polarized to enhance the ponderomotive effects. Microfocusing however rapidly decreases when particle necks evolve, and should merely occur in the early stages of sintering.

In spite of a significant number of papers indicating the effectiveness of these non-thermal effects, it is indeed difficult to evaluate, and even more to predict the amplitude of these effects and their importance for practical applications in ceramics processing.

Towards Applications in Ceramics Production

Although efficient, the microwave sintering technique still has a limited number of known applications in industry. Recent review papers (Bhattacharya and Basak, 2016; Oghbaei and Mirzaei, 2010) clearly listed the advantages of microwave sintering when compared to conventional heating techniques of ceramic industry: lower energy consumption, higher heating rates and time reductions, and in some cases improved properties associated to high heating rates or some non-thermal effects of microwaves. These advantages were only expected 30 years ago, as pointed out by Katz (1992), but significant technical and scientific progress has occurred since these early works. Evaluations on some practical cases showed very significant shorter sintering times and cycle times: for instance, when conventional sintering of a Y-TZP part requires 60 min sintering time, 6 h processing time, and more than 4 kWh, microwave sintering enabled to obtain the same final properties with 20 min, 1.5 h, and 0.4 kWh, respectively (Zhao *et al.*, 2000). Microwave furnaces of various types (muffle furnaces, batch or pusher kilns, gas and vacuum furnaces), sizes (from 50 cm to several meters), enabling processing temperature up to 1600°C and more, have been developed by different providers all over the world and can be seen on their websites. Some of them, said *hybrid kilns*, associate microwave with another heating technique (gas, electric power) which ensures reaching temperature at which materials efficiently couple with microwaves. However, the microwave technique is not much implemented in the ceramic industry and remains limited to the laboratory scale or specific applications. There is indeed few information available from ceramic manufacturers, but communication of some microwave furnace providers cites effective industrial applications with significant gains in processing time and energy consumption (Shulman *et al.*, 2008). Microwave sintering ovens are available for dentistry, which take advantage of the very simple use by dental technicians, fast processing and low energy consumption, and maybe of the small batches inherent to this production.

Limitations may come from the difficulty to ensure heating homogeneity. One of the consequences is the limited size of parts: 16 cm pieces are still considered as large and require careful attention and efforts for being obtained by microwave sintering (Chen *et al.*, 2016; Thuault *et al.*, 2014). The required investment can however become valuable in the future, as far as knowledge progresses, either for specific applications or for massive energy savings. Computer simulation and modelling as effective tools for understanding and design, should significantly contribute to make applications of microwave sintering effective in future in ceramic materials production.

Partial Sintering

A ceramic material is typically produced by sintering a powder compact. Both the degree of porosity and pore sizes in a porous monolith can be controlled by varying the initial particle size, green density, sintering additives and sintering condition during the heat treatment, so as to obtain varying degrees of densification. The initial and middle stages of sintering are very important in terms of creating the porous network, and different porosities and pore sizes can result from partial sintering techniques. Sintering always includes both densification and grain growth, with rounding of the angular, convex surfaces of particles occurring during the initial stage. Subsequent to this, adjacent particles in contact with one another bond together due to surface diffusion or evaporation–condensation processes. The material transfer from the particle surfaces to so-called neck regions through either surface diffusion or vapor transport does not decrease the distance between particle centers. That is, neither shrinkage nor densification takes place, while the neck areas between grains are enlarged during heating. This mass transfer can be greatly enhanced by applying a sintering temperature higher than that used during the initial sintering stage. The addition of carefully selected sintering aids can also promote neck growth along with grain boundary migration, followed by grain coarsening and densification in the middle and/or final stage of sintering. Through these sintering stages, the morphological changes of the grains can greatly affect various functional properties of porous ceramics, because the properties are directly correlated with pore size and porosity. Sintering a powder compact at an elevated temperature can increase the pore size because the pores are surrounded by large grains due to grain growth, while porosity is decreased due to densification, and vice versa. Thus, the particle size of the raw powder is also an important factor determining the pore size and porosity of the final product. Generally, the particle size of the raw powder should be two to five times larger than the desired pore size. However, even if the raw powder particle size and sintering conditions are properly tuned, it is frequently not possible to fully predict the resulting pore size and porosity of the sintered compact, due to the agglomeration of fine particles. For this reason, the raw particles are often subjected to ball milling (to break up such agglomerations) and high pressure forming, both of which are critical to obtaining the desired pore size and porosity in the final product. This partial sintering technique is the approach most commonly used to prepare many porous materials currently on the market, because it can easily be combined with the other techniques discussed in the following sections.

Fibrous Ceramics

Fig. 1 presents a typical image showing a fibrous ceramic microstructure. These ceramics are typically produced by blowing molten glass, natural rock or silicates in conjunction with a high-speed airflow and centrifugal force. Recently, very fine ceramic fibers with diameters of less than 10 μm have been developed, primarily made of mixtures of silica and alumina. The thermal stability of these materials decreases with increasing the silica ratio. Fibers with high silica content are usually produced by the melt blowing process

Fig. 1 The microstructure of fibrous ceramics used as thermal insulation in industrial furnaces and plants.

Fig. 2 The microstructure of various cellular ceramics prepared by (a) replica templating, (b) direct foaming, (c) extrusion and (d) gelation freezing.

described above, while ceramic fibers with lower silica contents can be manufactured by spinning a viscous sol solution prepared through the hydrolysis and condensation of an aluminum alkoxide. The latter process manufactures fibers having a higher alpha-alumina content that can be used at temperatures up to 1700°C. In these materials, the pores are formed from spaces between the fibers, and the properties are affected by their composition (silica/alumina ratio), fiber diameter, fiber length and volume fraction, as well as the degree of contact between adjacent fibers and the packing degree (density). Fiber boards, felts and blankets can all be produced by combining these ceramics with thermally cured organic or inorganic binders, followed by unidirectional pressing and laminating. These products have been widely utilized as thermal insulators in industrial furnaces, chemical plants and energy storage systems operating at elevated temperatures, because they can have very high porosity (above 90%) and narrow fiber diameters, and so have thermal conductivities typically less than 0.1 W/mK. As ceramic fibers do not include any volatile organic compounds, they have also been extensively utilized as building materials for sound absorption as well as thermal insulation. These materials can be readily processed and formed into various shapes at relatively low temperatures, as a result of their high degree of flexibility.

Cellular Ceramics

Fig. 2 presents typical microstructure of various cellular ceramics prepared by (a) replica templating, (b) direct foaming, (c) extrusion and (d) freeze casting (Ohji and Fukushima, 2012). Ceramic foams are typically manufactured by dip-coating a polymeric foam, acting as a replica template, into a ceramic powder dispersed as a slurry, a sol-gel precursor solution or a molten/liquid preceramic polymer, followed by burn-off or pyrolysis of the polymeric substrate and sintering. Typical microstructure is shown in **Fig. 2(a)**. This method is still the most widely used by industry for the manufacturing of ceramic foams for applications as molten metal filters or burners. A polymeric sponge, typically made of polyurethane, can be employed as the template material, but bio-derived porous materials such as wood or paper can also be used to create a cellular structure. However, because the expansion and gas evolution of the polymer during the burn-off step can damage the ceramic coating, it is challenging to create a defect-free ceramic coating on the template. This, plus the presence of voids inside the struts after elimination of the template tends to limit the mechanical strength of the ceramic foam, such that compression strength values are typically less than 1 MPa, albeit still suitable for some applications. The cell size of the foam generally ranges from several tens of micrometers to the millimeter

scale, and is primarily determined by the cell size of the original polymer template. Improvement of the strength can be achieved by multiple infiltration and sintering procedures.

A great variety of alternative processing approaches have been proposed for the fabrication of ceramic foams having improved mechanical properties. Direct foaming is based on the introduction of a gas into a liquid (either a slurry or sol solution) or softened polymer (a molten preceramic polymer with a thermoplastic binder) and the typical microstructure of the products is shown in [Fig. 2\(b\)](#). The gas can be introduced by various routes, such as mechanical frothing (mixing to generate bubbles), phase separation (segregation of a dissolved gas), in situ gas generation by a chemical reaction, thermal decomposition of a blowing agent, or the evaporation of a solvent. Various methods have been proposed to stabilize bubbles during this process so as to create fine, possessing the desired interconnectivity in the final porous bodies. These include the use of surfactants, the evaporation of emulsified alkane droplets and the use of surface-modified particles to prevent Ostwald ripening and coalescence among gas bubbles contained in the suspension (which otherwise lead to an inhomogeneous pore size distribution or the collapse of the liquid foam). The final microstructure frequently exhibits an anisotropic size gradient, associated with the floating direction of bubbles generated in the slurry, molten preceramic polymer or sol solution. [Shimamura et al. \(2016\)](#) developed a dry foaming method to mitigate this phenomenon. In this process, a powder compact containing a thermoset resin is foamed at a temperature that softens the polymer but is lower than the curing temperature. The morphology can be relatively homogeneous, because the particles are not strongly affected by buoyancy forces.

[Fig. 2\(c\)](#) shows the microstructure of a ceramic honeycomb. These materials have a substantial market position in catalytic converters, heat exchangers, combustors and filters and are manufactured by extrusion, conventional binder burn-off and sintering processes. In the case of extrusion, the die can be designed to produce a wide variety of cell geometries, such as square, triangular and hexagonal. The extrusion process requires the use of moldable natural clay or fine ceramics as raw materials, together with water and/or a binder having a degree of plasticity. This is required to ensure adequate rheological behavior of the mixture as well as structural rigidity and stability without excessive die wear. The size ratio between the die and container in which the raw mixture is held is also important.

Another novel processing method that enables the fabrication of unidirectional pore channels is the freeze casting of slurry or a gel body containing raw ceramic particles or ceramic precursors. The porous structure is templated by solidifying a solvent (typically water, although tert-butyl alcohol and camphene can also be used), leading to unique morphologies, such as lamellar, ellipsoidal or dendritic structures grown along the solidification direction. The freezing process generates porosity in the slurry or gel body, due to sublimation under vacuum of the solvent crystals, and is followed by sintering. This method produces materials with very good mechanical properties (such as compressive strength) along the freezing direction, because the struts are surrounded by cells aligned parallel to this direction within the entire sample. Pioneering work in this field was performed by [Fukasawa et al. \(2001\)](#), while [Fukushima et al. \(2010\)](#) proposed a gelation freezing process. Applying this method under carefully controlled freezing conditions, unidirectional cellular structures with very high porosity (up to 98 vol%) based on micrometer sized cells can be prepared, as shown in [Fig. 2\(d\)](#). The resulting cellular components possess substantially improved fluid permeability close to the ideal value calculated based on the capillary model, and very high mechanical strength due to micrometer-sized unidirectional structures without any defects. These cellular materials could be used as catalyst supports and for filtration, thermal insulation and biomedical applications, as well as lightweight structural components.

In addition to the various methods described above, the degree of porosity can be increased through the elimination of sacrificial fugitive additives acting as pore forming agents and mixed with raw ceramic particles or preceramic polymers. These are burned off or evaporated either before or during sintering of the particles or during pyrolysis of the polymer. This technique allows for the precise control of the degree of porosity and the pore size distribution and tends to give a wider range of cell sizes, typically from several tens of nanometers to the submillimeter range ([Colombo and Bernardo, 2003](#)). This method can be applied by itself or combined with other fabrication routes, such as partial sintering, templating, extrusion or blowing. Polymer beads, organic fibers, carbon, natural organic matter and liquids (water, gels and emulsions) have all been used as sacrificial pore forming agents, while poly(methylmethacrylate) (PMMA) beads have been most frequently employed as sacrificial additives, because that can be thermally decomposed and certainly removed.

Additive Manufacturing

Additive manufacturing (AM) is a promising new technique with the potential to change conventional industrial manufacturing processes. This process has been used to manufacture ceramics having non-stochastic porous structures for the applications as scaffolds for biological applications, filters and lightweight materials ([Zocca et al., 2015](#)). AM also allows for the fabrication of porous architectures having complex shapes together with precisely-controlled pore dimensions, shapes and volume fractions, which cannot be achieved by any other technology currently used for the production of macro-porous bodies. However, the technologies that are suitable for the fabrication of fine porous structures have shortcomings when scaled up to generate large bulk parts and vice versa. Thus, methods that are well-suited to the fabrication of dense materials may have difficulties in producing highly porous, fine geometries. The AM researches on porous products have been so far substantially devoted to the shaping of biomedical scaffolds for tissue engineering, although the possibility of generating catalyst supports with a well reproducible geometric surface and optimized flow properties is gaining attention.

AM methods can be classified, according to ISO/ASTM 52900:2015, “Additive manufacturing – General principles – Terminology”. Sintered porous ceramic bodies are usually not prepared by AM, because that requires high temperature heating above 1200°C. Thus, AM has been generally utilized to prepare green bodies, followed by sintering. Among AM methods, binder jetting has been widely used to create porous green body. Binder jetting is especially applicable to the formation of porous ceramic structures. In this process, a solid structure is produced by the sequential deposition of layers of a flowable powder. Each layer of the powdered substrate material is spread out, after which the desired morphology is selectively inscribed using an ink-jet printing head that selectively deposits a liquid binder. This process is repeated until the object is complete, thus producing a final product that is completely contained in a powder bed from which it can be easily extracted and cleaned. Residual porosity (up to 50 vol%) is always present in the sintered body, due to the requirement of using coarse powders to enable particle flowing when generating each layer. An alternative process, powder bed fusion, a laser beam induces local densification of the powder either by direct sintering of the ceramic or by melting a binder phase mixed in with the ceramic powder. In order to obtain porous products, the binders within the powder must be thermally cured. One challenge associated with this process is that the direct laser sintering of ceramics is complicated by the poor resistance of ceramic materials to thermal shock. The direct deposition of ceramic slurries, i.e., material extrusion, is also an AM technology often used to fabricate porous structures. In such process, a viscous ceramic paste or preceramic polymer is extruded through a nozzle or orifice to produce a filament. The rheological properties of this paste or preceramic polymer are critical to preventing deformation or sagging, especially when the geometry includes spanning features, as in most porous components.

Introduction

For structural applications of brittle ceramic materials, the presence of porosity is generally considered problematic because the pores act as defects and crack initiation sites and degrade the mechanical reliability. However, there are many engineering applications, where the presence of pores can be advantageous, ranging from refractories, filters, membranes, absorbents, catalysts and catalyst supports to lightweight structural components and thermal insulators. While ceramic materials can exhibit useful intrinsic properties such as thermal and chemical stability, and excellent mechanical properties, the presence of porosity provides decreased density, additional surface area, thermal or electrical insulation, energy absorption, and fluid permeability. Porous materials can be described according to the average pore size, the pore size distribution, the volume fraction of pores (total porosity), and the degree of interconnectivity among the pores (ratio between open and closed pores). These morphological features affect all the properties of porous ceramics, such as density, mechanical strength, adsorption, permeability to fluids, and thermal/electrical insulations. Comprehensive reviews on macroporous ceramics, processing and properties have been written by Colombo (2006), Studart *et al.* (2006), and Ohji (2012).

This chapter focuses mainly on cellular ceramics, including fibrous insulation, and their structure and properties.

Structure and Properties of Highly Porous Ceramics

Fibrous Ceramics

Ceramic thermal fibrous insulators have been extensively utilized in the form of blankets, felts, or monoliths in high temperature furnaces and industrial plants, because their very high porosity and narrow fiber diameter reduce heat transfer. The performance and shape of the fibrous insulators can be freely changed depending on their flexibility. Fibers are usually produced by blowing of molten silicates or by the sol–gel route, via hydrolysis and condensation of alkoxides. Figure 1 shows a typical example of a fibrous insulator. Fibrous insulators generally possess very low thermal conductivities of around $0.1\text{--}0.2\text{ W mK}^{-1}$ or less. In the fibrous insulators, the solid conduction and radiation contributes to the effective thermal conductivity can be controlled by adjusting their microstructural characteristics, such as the fiber diameter, volume fraction of fibers, and packing density. The solid conduction in fibrous insulators can be affected by the conduction through the solid phase (fiber), and conduction from the solid phase to air (and vice versa). Thus, smaller fiber diameters with narrow transfer paths can decrease the thermal conduction. The solid conduction contributes to the total conductivity according to the volume fraction of the solid phase. The radiation transfer also contributes to the effective conductivity of an insulator, particularly at elevated temperature. Most of oxide ceramics are relatively transparent to wavelengths in the near infrared region, although the thermal radiation for oxide fibrous insulators can be intensively scattered by the effect of microstructural features such as the air–solid interfaces, the shape of the pores, and the fiber diameter in the insulators. Verschoor (1952) reported that, in the temperature range of $500\text{--}1200\text{ }^{\circ}\text{C}$, silica fibrous insulators with a fiber diameter of $1\text{--}3\text{ }\mu\text{m}$ exhibited lower thermal conductivity than those with a fiber diameter of $10\text{--}15\text{ }\mu\text{m}$, because of the effect of radiative scattering on the thermal conductivity at elevated temperature. However, at room temperature, there is a limited effect of radiative thermal transfer on the total conductivity. Although the thermal conductivity of silica fibrous insulators with porosity of 95–99 vol% was reported to be around 0.04 W mK^{-1} at room temperature, the radiation contribution is negligible.

Cellular Ceramics

A wide range of processing methods has been proposed for the production of cellular ceramics. Figure 2 shows various morphologies of cellular ceramics as examples. Each fabrication method results in a different morphology of the cellular architecture and different properties depending on the cell size, distribution, shape, and interconnection, the cell wall thickness, the volume fraction of pores as well as the composition used.

Figure 2(a) shows the morphology of partially sintered porous alumina. Particles of powder compact are bonded at the appropriate sintering temperature that should be lower than the sintering temperature used to prepare fully dense materials. The formation of thick and strong inter-particle necks can be achieved by employing adequate processing factors such as starting

Figure 1 Structure of fibrous ceramics used as thermal insulation in industrial furnaces and plants.

Figure 2 Structure of cellular ceramics prepared through (a) partial sintering, (b) replica templating, (c) gelation freezing (Reproduced with permission of Elsevier. All rights reserved.), and (d) direct foaming (Reproduced with permission of Elsevier. All rights reserved.).

particle size and size distribution, green density, and sintering conditions (the type and amount of sintering additives, temperature, time, atmosphere, pressure, etc.). Thus, a precise control of the initial or middle stage of sintering, occurring typically through surface diffusion, is required to manipulate the thickness of the inter-particle necks, because that affects the mechanical strength of the final products.

Ceramic foams, shown in **Figure 2(b)**, are typically manufactured by dip-coating a polymeric foam into a ceramic powder dispersed slurry or sol-gel derived precursor solution or a molten/liquid preceramic polymer, followed by burnout of the polymeric substrate and sintering (pyrolysis). This method is still the one mostly adopted by industry for the manufacturing of ceramic foams used as molten metal filters or burners. Concerning the replica template, a polymeric sponge, typically made of polyurethane, can be used, but bio-derived porous materials such as wood or paper can be also used to create a cellular structure. However, due to fact that struts can crack during the burn off the host substrates, the difficulty to create a homogeneous and defect-free ceramic particles coating on the template, and the presence of a void in the struts after the elimination of the template, the mechanical strength of these porous ceramics is quite limited (typically, the compression strength is not higher than 1 MPa). Thus, a great variety of approaches has been proposed to produce ceramic foams possessing improved mechanical properties using alternative processing methods. Cell size of the foams generally ranges from several tens of micrometers to millimeters.

Porosity can be created through the elimination of sacrificial fugitive additives as pore forming agents, mixed with ceramic raw particles or preceramic polymer, by burning out or evaporating the fugitive phase before or during sintering the particles or pyrolyzing the polymer, providing precise control on the average pore size distribution, with a wider range of cell size, typically ranging from several tens of nanometers to submillimeters, and amount of porosity. This method can be applied by itself or combining that with other fabrication routes. As sacrificial pore forming agents, polymer beads, organic fibers, carbon, natural organic matter, and liquids (water, gels, and emulsions) have been used. Polymethylmethacrylate (PMMA) beads have been frequently employed as sacrificial fugitives.

Another novel processing method, that enables the fabrication of unidirectional pore channels, is the freeze casting of a slurry or a gel body containing ceramic raw particles or ceramic precursors. The porous structure is templated by solidifying a solvent, typically water but tert-butyl alcohol and camphene can also be used, leading to unique morphologies such as lamellar or ellipsoidal or dendritic structures grown along the solidification direction. In this freezing process, porosity is created, after the freezing of the slurry or gel body, by sublimation by vacuum drying of the solvent crystals and subsequent sintering. This method allows to obtain very good mechanical properties (compressive strength) along the freezing direction, because the struts are surrounded by cells aligned parallel to freezing direction within the whole sample. A pioneering work in this field was carried out by Fukasawa *et al.* (2001). Fukushima *et al.* (2014) proposed the gelation freezing process. By applying this method under carefully controlled freezing conditions, uniformly arranged honeycomb-like structures with very high porosity (up to 98 vol%), comprised of micrometer-sized cells, can be prepared, as shown in Figure 2(c). The cellular components obtained possess substantially improved fluid permeability, comparable to the ideal permeability computed by the capillary model, and very high mechanical strength due to micrometer-sized honeycomb structures without any defects. Deville *et al.* (2007), and Devilles (2008) systematically discussed the solid/liquid interface kinetics which control the morphology of ice-derived structures. These cellular materials with micrometer-sized cell size could be used for catalyst support, filtration, thermal insulation applications, biomedical applications as well as lightweight components.

Direct foaming consists of the introduction of gas into a liquid (slurry or sol solution) or softened polymer (molten preceramic polymer and thermoplastic binder), as shown in Figure 2(d). Gas can be introduced by various routes, such as mechanical frothing (mixing to generate bubbles), phase separation (segregation of a dissolved gas), in situ gas generation by a chemical reaction, thermal decomposition of a blowing agent, or the evaporation of a solvent. Various methods to stabilize the bubbles have been proposed to create fine and controlled pores in the final porous bodies, including use of surfactants, evaporation of emulsified alkane droplets, and use of surface-modified particles to prevent Ostwald ripening and coalescence among gas bubbles contained in the suspension, which would lead to an inhomogeneous pore size distribution or the collapse of the liquid foam.

The novel processing routes discussed above lead to cellular ceramics possessing improved mechanical properties. Several models have been proposed, particularly by Ashby *et al.* (1983) and Gibson (2005), to predict the mechanical response of cellular ceramics as a function of relative density (or the amount of porosity), according to different microstructural models for porous components with open cells, closed cells, or honeycomb-like structure.

Introduction

The microstructure of ceramics can be defined as the arrangement of grains (individual crystals) and pores of different size and shape and occasionally of a crystalline or vitreous intergranular phase. This microstructure is generated at the end of the densification process from a powder compact following heat treatment. No microstructure is perfect and homogeneous and it is strongly dependent on powder characteristics and sintering mechanism. The matter transport to reduce the porosity of a powder compact occurs at high temperature by:

- (1) diffusion of atoms through the crystal lattice (D_l), along the surface (D_s) or the grain boundaries (D_b) in the absence of liquid phase,
- (2) dissolution-diffusion-precipitation mechanisms in the presence of a liquid phase, or
- (3) by viscous flow in the case of a large amount of liquid phase.

In all cases, there is a competition between the densification⁷⁷ phenomenon and grain growth which strongly impacts the final grain size. As most of the ceramic properties, particularly sensitive properties such as mechanical resistance or electric conductivity depend on microstructure, it is therefore crucial to control all the steps leading to the microstructural development.

Microstructure can be controlled by optimization of each of the fabrication process steps:

- (1) careful choice of raw materials particularly taking into account the chemical purity and particle size and shape,
- (2) selection of the appropriate shaping technology with optimized parameters, and
- (3) optimization of the temperature–time schedule and furnace atmosphere during sintering (air, O₂–Ar, Ar, N₂, water,...).

As examples, Fig. 1 illustrates the appearance of microstructural defects:

- (1) porosity induced by the presence of an uncrushed alumina granule remaining after pressing step due to non-optimized slurry for the spray-drying operation,
- (2) exaggerated grain growth due to non-optimized sintering conditions.

In addition, the thermal treatment can be modified, for example using:

- (1) pressure assisted methods such as Hot Pressing, HIP, Post-sintering HIP treatments, where the driving force includes an extra parameter related to external pressure ($2\gamma/r + P_{\text{ext}}$),
- (2) methods such as Spark Plasma Sintering and Flash Sintering where the application of an electrical field induces increases in densification rates, and
- (3) microwaves, a process which involves more homogeneous heat source distribution.

Fig. 1 Examples of microstructural defects. (a) porosity induced by the presence of an un-crushed alumina granule remaining after pressing step, (b) exaggerated grain growth in spinel due to non-optimized sintering conditions. The purpose of this chapter is to describe the various strategies allowing a better control of the microstructure for ceramic materials in order to counteract the presence of defects.

Microstructural Development During Ceramic Processing

The fabrication of ceramic materials commonly starts from a compacted powder, which is converted into a dense solid by heat treatment.

Most green bodies fabricated by various shaping techniques possess relative densities between 50% and 60% which means that at least 40 vol% of porosity has to be eliminated during sintering and densification of the part is accompanied by a large shrinkage (decrease of dimensions) of about 35–40 vol% (i.e., 18–20 linear%).

The densification driving force ($2\gamma/r$) activated by temperature can be (1) macroscopically viewed as the decrease of free energy as solid-vapor interfaces are replaced by solid-solid interfaces and (2) microscopically viewed as the free energy (pressure) difference across a curved grain boundary. In the absence of liquid phase, the matter transfer occurs by atom diffusion through different paths: lattice, grain surface, grain-boundary or vaporization and condensation on grain surfaces. Only diffusion through the lattice and grain-boundaries leads to shrinkage of the powder compact although the surface phenomena induce changes in particle shape and grain growth without shrinkage.

The densification occurs within 3 stages with accompanying changes in pore content and geometry as shown in Fig. 2:

- (1) initial stage, during which necks are growing at contact points between particles,
- (2) intermediate stage (65%–90% density), during which pores become cylindrically shaped with interconnections, so-called “open porosity”,
- (3) final stage (90%–100% density), during which pores become more spherical and isolated: “closed porosity”.

During this last stage, grain growth becomes predominant compared with densification because of the driving force decrease. The larger grains grow at the expense of the smaller ones. This phenomenon has been well observed by combined HT-ESEM/dilatometry by Clavier *et al.* (2013) for ThO₂ powders (Fig. 3).

As shown in Fig. 3, the grain growth rate becomes predominant versus densification rate during the last stage of sintering and the microstructure shows a polycrystalline ceramic with a dispersion of isolated pores located at the grain boundaries. The pore mobility is as slow as its size is large.

Two hypotheses are invoked to explain the phenomena:

- (1) the pore stays immobile and the grain boundary overcomes it so that the pore becomes isolated. In this case, further pore elimination becomes very difficult.
- (2) the pore can move with the grain boundary as illustrated in Fig. 4. The pore surface located towards the center of curvature of the grain boundary possesses a larger radius of curvature than that of the other face which causes atom flow from the back surface to the front one. This atom flow can occur by lattice, surface or vapor diffusion and the pore moves towards the center of curvature of the boundary.

When the pore is mobile, the boundary migration rate is controlled either by its intrinsic mobility or by the pore mobility. If the boundary moves faster than the pores, a separation between the pore and boundary occurs. As illustrated in Fig. 5, which shows the relationship between grain size and pore size when the atom flow is managed by surface diffusion, this separation phenomenon occurs in the region above the domain where the grain growth is controlled by the pore mobility (slope +1) and below the domain where the grain growth is controlled by the boundary mobility (slope +3). The intersection of the 2 straight lines corresponds to the critical grain size above which a pore/ boundary separation can occur (Fig. 5).

Fig. 2 Schematic illustration of grain compaction and pore shape changes during sintering.

The same types of map can be constructed for the other pore mobility mechanisms like volume diffusion or vapor diffusion and present the same configuration. These maps are beneficial in determining the optimal trajectory to avoid the pore-boundary separation. Therefore, it is necessary to decrease the pore size before grain growth starts. For that, several strategies can be adopted that are described in the following paragraphs.

In presence of liquid phase, the capillary pressure results in densification via a dissolution-diffusion-precipitation mechanism. In such a case, grain growth can be controlled either by the dissolution step or by the diffusion step. If the grain growth kinetics are controlled by the dissolution step, it will depend on various parameters such as atom volume, temperature, solid/liquid surface energy, molar content of solute in the liquid phase and atom transfer rate between crystal and liquid. If the kinetics are controlled by the diffusion step, it will depend on atom diffusion coefficient in the liquid.

As this grain growth phenomenon can be deleterious to some ceramic properties, it is necessary to develop different ways of achieving high densification rates by limiting grain growth during sintering.

Strategies to Control Microstructural Development

Choice of Powder Characteristics

It should be noted that the most important parameter influencing densification and grain growth is the powder characteristics and in particular its mean size and grain size distribution. Thus, narrow grain size distribution is preferable for obtaining a high density. A theoretical approach carried out by M.I.T. (Barringer and Bowen, 1982) showed the existence of a limiting density value as a function of the grain diameter distribution expressed as the ratio: D_{max}/D_{aver} . This ratio would be ≤ 2 to avoid the pore separation from grain boundary as illustrated in Fig. 6.

This was experimentally confirmed by the work of Barringer and Bowen (1982) for a submicron TiO_2 powder which was fully sintered at 300K below the temperature normally required for a powder with the usual grain size distribution.

The influence of different crystallographic phases in a powder on sintering and subsequent mechanical properties is well illustrated by the microstructural development of silicon nitride ceramics. The strong covalent bonds impede pressureless sintering due to low self-diffusivity; consequently oxide dopants have to be added which allows formation of an oxynitride liquid phase leading to densification at 1750°C, below the silicon nitride decomposition temperature. The mechanism of dissolution of the predominant α phase in the liquid phase followed by diffusion and precipitation of the β phase onto β - Si_3N_4 seeds already present in the initial powder as the minor constituent is illustrated in Fig. 7. The resulting microstructure, which consists of elongated and

(Ed.), *The Physics and Chemistry of Carbides, Nitrides and Borides*. NATO-ARW Series. Kluwer Academic Publishers, pp. 13–28.

crosslinked β -Si₃N₄ grains with an amorphous oxynitride intergranular phase, is favorable for high ceramic toughness (up to ~ 11 MPa $\sqrt{m}$), mainly by crack bridging and crack deviation mechanisms (Fig. 8). The development of this favorable microstructure depends on the α -to- β conversion rate which is a function of the content of β phase seeds in the initial powder as reported in Fig. 9

Choice of Optimal Sintering Parameters: Temperature, Time, Heating Rate

In Section “Microstructural Development during Ceramic Processing”, it was explained that temperature favors the densification rate but also that the concurrent grain growth phenomenon becomes predominant during the final stage of densification. A close control of the temperature cycle is therefore needed to obtain the optimum microstructure. Several sintering methods are based on heating rate control.

Fig. 11 Densification rate or grain growth rate as a function of temperature. Adapted from Harmer, M.P., Brook, R.J., 1981. Fast firing – Microstructural benefits. *Transactions & Journal of the British Ceramic Society* 80, 147–149.

Controlled rate sintering

This technique was proposed by Palmour III and Johnson (1967). It allows optimization of grain size and pore elimination by maintaining the densification rate constant at relative densities greater than 0.75 to favor grain boundary diffusion, D_b , rather than surface diffusion, D_s which is deleterious to shrinkage (Fig. 10).

Fast sintering

The objectives of the following methods are to heat a powder compact at much higher heating rates than in conventional sintering in order to reduce the dwell time during the low temperature range which favors densification with minimal grain growth.

The first method, called “Fast Firing”, was proposed by Harmer and Brook (1981) as a sintering method in order to enhance densification and suppress grain growth and consists of the introduction of green samples rapidly into the hot zone of a furnace so that the samples attain higher temperatures very quickly where the activation energy for densification, Q_p , is higher than Q_g , the activation energy for grain growth as shown in Fig. 11. Fast firing thus allows a powder compact to reach temperatures above an intermediate temperature, T_{int} , very quickly thus minimizing grain coarsening during heating.

Unfortunately, this technique has to be restricted to small-sized samples because of the large thermal gradients generated by fast heating and cooling. For instance, small disks of barium titanate capacitors can be sintered by this method.

Fig. 12 illustrates the finer microstructure obtained for fast fired (FF) yttria doped zirconia ceramics (YSZ) compared to conventional sintering (CS). CS samples presented larger grain sizes by a factor of ~ 2 to ~ 4 in comparison with the initial 3YSZ (3 mol.% Y_2O_3) and 8YSZ (8 mol.% Y_2O_3) powders. Conversely, the FF method significantly suppressed grain growth with a growth factor of ~ 1 . (Gómez et al., 2016).

The second method is to use microwave assisted firing techniques that allows direct coupling of the microwaves with electric dipoles within the ceramic which results in high heating rates and therefore avoids the lower temperature region where the rate of grain growth is higher than the rate of densification (Binner and Vaidhyanathan, 2008). Full density can be achieved within a few

Fig. 13 Arrhenius-type plots of densification rate in 55 to 90% relative density range, measured during conventional (CS) sintering and direct microwave (MW) sintering of alumina powder compacts at various heating rates (from 1.6 to 158°C/min). Adapted from Croquesel, J., Bouvard, D., Chaix, J.M., *et al.*, 2016. Direct microwave sintering of pure alumina in a single mode cavity: Grain size and phase transformation effects. *Acta Materialia* 116, 53–62.

minutes. Croquesel *et al.* (2016) have shown that the use of microwaves to sinter alumina powder compacts results also in a significant decrease of the densification activation energy from $518 \pm 18 \text{ kJ mol}^{-1}$ for conventional heating to $301 \pm 14 \text{ kJ mol}^{-1}$ which proves the existence of a “microwave effect” (Fig. 13).

Two-step sintering (TSS)

This technique exploits the difference in kinetics between grain boundary diffusion leading to elimination of porosity and grain boundary migration responsible for grain growth (Chen and Wang, 2000). There are different ways to apply the two step sintering method. The first one was developed by Chu *et al.* (1991) and consisted of a first stage at a relatively low temperature, over a long period of time, to perform pre-coarsening of grains to achieve a uniform grain size distribution; this is followed by a second stage at higher temperature to finalize the densification (Fig. 14). The technique was applied by Lin *et al.* (1997) for microstructural refinement of alumina with a pre-coarsening step at 800°C for 50 h followed by a second dwell at 1450°C. In normal direct sintering, smaller particles densify faster resulting in uneven pore size distribution which leads to non-uniform grain size distribution in the later stages. In TSS, pore channels become smoother after pre-coarsening and the longer time at lower temperature allows smaller grain sizes with narrower grain size distribution which can be explained by minimization of differential densification and resulting delay of the pore channel closure to achieve higher density. The TSS technique was also applied to silicon nitride ceramics without using β -Si₃N₄ seeds. The first step allows the α -to- β phase transformation without densification whilst the second step promotes densification and grain growth (Kim *et al.*, 2002).

Fig. 14 Schematic of a typical two-step sintering schedule. As used by Chu, M.-Y., De Jonghe, L., Lin, M.F.K., Lin, F.J.T., 1991. Precoarsening to improve microstructure and sintering of powder compacts. *Journal of the American Ceramic Society* 74 (11), 2902–2911. Chen, L.W., Wang, X.H., 2000. Sintering dense nanocrystalline oxide without final stage grain growth. *Nature* 404, 168–171.

Fig. 15 Grain size versus density of Y_2O_3 as a result of TSS. After Lóh, N.J., Simão, L., Jiusti, J., De Noni Jr., A., Montedo, O.R.K., 2017. Effect of temperature and holding time on the densification of alumina obtained by two-step sintering. *Ceramics International* 43, 8269–8275.

Chen and Wang (2000) changed radically the concept of TSS by inverting the temperature dwells. In their work, the ceramic body (Y_2O_3) was rapidly subjected to a high temperature for a short time and was subsequently cooled and kept at a lower temperature until densification was complete (Fig. 15). Fig. 15 shows the results of applying this inverted temperature TSS approach to a study of densification of Y_2O_3 . It is clear that almost no grain growth occurs during the second stage of the process compared with normal sintering (Lóh *et al.*, 2016).

The microstructure of an alumina powder obtained using the TSS method is compared with one conventionally sintered (C) in Fig. 16. This illustrates very well the achievement of full density without grain growth in the case of TSS (Lóh *et al.*, 2017).

Pressure and/or Electric Field Assisted Sintering

The idea is to increase the driving force for densification ($2\gamma/r$) which arises from free energy differences across a curved grain boundary. This may be estimated at around 1–2 MPa and by adding external pressure ($2\gamma/r + P_{\text{ext}}$), densification is enhanced by modifying the pore stability conditions allowing the elimination of smaller sized pores. Several methods such as hot pressing, hot isostatic pressing and spark plasma sintering obey this principle.

Hot pressing (HP)

Hot pressing involves the application of a uniaxial pressure through a simple shaped die. The use of such an applied pressure (10–30 MPa) at the sintering temperature increases the densification rate and the ability to reach near-theoretical density in a

Fig. 16 SEM observations of microstructures of pure (> 99.7%) alumina powders densified up to 99% relative density by conventional sintering (C) at 1600°C for 10 h holding time, and by two-step sintering (TSS) $T_1 = 1450^\circ\text{C}$, $t_1 = 5$ min, $T_2 = 1500^\circ\text{C}$, $t_2 = 4$ h. Effects of applied pressure on densification during sintering in the presence of a liquid phase. *Journal of the American Ceramic Society* 46, 391–395.

reasonable time. It is generally considered that several simultaneous mechanisms contribute to densification during hot-pressing. As well as diffusion, enhanced by the applied pressure, grain-boundary sliding and plastic flow have some effect. A significant grain size reduction is obtained by this method, as illustrated in Fig. 17 which shows the changes in relative density and grain size of MgO ceramics with temperature when hot pressed under different pressures. With a liquid phase present, the applied pressure is thought to be merely additive to the capillary pressure (Kingery *et al.*, 1963).

Hot isostatic pressing (HIP)

Hot isostatic pressing (HIP) combines high temperature (up to 2200°C) and a gas pressure (200–500 MPa), which is uniformly applied to the powder compact in all directions, usually through an impermeable membrane to encapsulate the ceramic component. Almost full density with no open porosity can also be achieved by HIP directly without encapsulation. This technique allows theoretical density to be reached with limited grain growth where this may not be possible by conventional pressureless sintering.

As an example, post sintering treatment by HIP (referred to as post-HIP) is currently used to fully eliminate residual porosity during fabrication of transparent ceramic parts. Fig. 18 shows the transparency obtained when the porosity is completely eliminated by post-HIP treatment.

Fig. 18 First row: Visual aspect of disks, and Second row: SEM micrographs of MgAl_2O_4 spinel after (a) pressureless sintering, at 1500°C for 2 h, (b) after post-HIP at 1500°C for 10 h, and (c) after post-HIP at 1800°C for 1 h. Influence of post-HIP temperature on microstructural and optical properties of pure MgAl_2O_4 spinel: From opaque to transparent ceramics. *Journal of the European Ceramic Society* 37, 5347–5351.

Spark plasma sintering (SPS)

More recently, electrical field assisted sintering techniques have been developed. Spark plasma sintering (SPS—**Fig. 19(a)**), also known as pulse electric current sintering or field assisted sintering technique (FAST), uses an electrically conducting pressure die (graphite) containing the green powder compact which is then subject to applied pressure and a pulsed electric current (Nygren and Shen, 2003). The die provides heat externally to the powder compact, but, if the ceramic has sufficient electrical conductivity, heat is also generated internally which leads to rapid heating rates in the range $100\text{--}1000^\circ\text{C min}^{-1}$. This enhances material diffusion and allows full density to be achieved with limited grain growth at comparatively low sintering temperatures, typically a few hundred degrees lower than in normal hot pressing (HP) after very short holding times (a few minutes).

Fig. 19(b) shows the relative densities obtained for submicron pure ($>99.7\%$) alumina powder sintered at different heating rates using SPS (FAST), Resistive Hot-pressing (HP) and Inductive Hot-pressing (HPind) techniques. As can be noted, densities are between 85% and 98%, after 6 min dwell time at 1600°C , under 16 MPa. Such densities were achieved by SPS depending on heating rate whereas densities of only 70% were achieved by HP under similar conditions.

The positive effect of current application on densification could be due to a number of factors:

- (1) the enhancement of surface phenomena like surface diffusion which favors neck formation explaining low temperature “advantage”,
- (2) the electromigration observed in conductive materials, or
- (3) the generation of charges at the particle surfaces due to impurities in the powder.

Fig. 20 compares grain size as a function of relative density for the same submicron pure ($>99.7\%$) alumina powder as in **Fig. 19** sintered using SPS, HP (resistive) and HPind (Inductive). Grain growth only becomes predominant once relative density reaches around 98% and smaller grain size is obtained by SPS during this last stage of densification compared with HP.

Flash sintering (FLASH)

Flash sintering involves heating a ceramic powder compact in a conventional sintering furnace and simultaneously applying a dc or ac electric field. The green sample, often in a “dog-bone” shape, is attached to two platinum electrodes allowing the passage of current. At high fields, the specimens sinter to high densities almost instantaneously above a critical temperature, hence the term Flash Sintering as used by Raj R. (Raj *et al.*, 2011; Yoshida *et al.*, 2014; Jesus *et al.*, 2016; Mishra *et al.*, 2020). In some of the first

experiments (Cologna *et al.*, 2010) yttria-stabilized zirconia was sintered in a few seconds at $\sim 850^\circ\text{C}$ to full density, starting from a green density of 50%, by the application of a dc electric field. Normally, a temperature of 1450°C is required over several hours to complete the densification. This can be explained by local Joule heating at grain boundaries, which promotes grain-boundary diffusion (a kinetic effect), and at the same time hinders grain growth (a thermodynamic effect). Several oxides have been sintered using this technique such as cobalt-manganese spinel, MgO-doped alumina, and cubic and tetragonal zirconia but the fundamental mechanism of the very rapid mass transport involved remains obscure.

Fig. 21 compares the linear shrinkage for conventional and several electric fields assisted sintering experiments conducted on BaTiO_3 specimens, from 0 to 150 V cm^{-1} (M'Peko *et al.*, 2014). Without an electric field (0 V), the samples densify slowly as the temperature rises. The application of an electric field results in nearly instantaneous densification. The threshold temperature for the onset of flash sintering moves lower as the electric field increases.

Similar experiments were conducted on zirconia samples. Fig. 22 shows the comparison of conventionally and flash sintered zirconia samples with $1 \mu\text{m}$ initial particle size, it can be seen that grains of less than 100 nm are more heavily populated in the flash-sintered specimen.

There is growing evidence that oxides of complex chemistries, for example $\text{CaCu}_3\text{Ti}_4\text{O}_{12}$, can be formed in one step by reactive flash sintering of their constituent oxides (Jesus *et al.*, 2016).

Composition Modification

Addition of dopant elements to modify grain boundary energy

Dopants are very often introduced to modify grain boundary energy. The dopant may be partially soluble in the major component (Region I in Fig. 23) but eventually the solubility limit is reached, above which segregation occurs at grain boundaries (Region II in Fig. 23). Grain boundary mobility is slowed down by segregated dopant ions. The maximum concentration of segregated dopant at grain boundaries increases with surface to volume ratio of the grains, i.e., it is higher for nanosized grains. Above a given

concentration, a new (dopant-rich) phase precipitates and this occurs at lower dopant concentrations as grain size increases (Region III in Fig. 23).

Fig. 24 shows grain boundary segregation or precipitation of YAG for Y^{3+} -doped alumina as a function of grain size and dopant concentration. As Y^{3+} concentration increases, the precipitation of YAG suppresses grain growth.

Fig. 25 compares grain growth rates for pure and MgO-doped alumina and shows clearly the effect of the dopant in restricting grain growth.

Fig. 26 presents an example of the combined effects of using SPS and yttria doping for a zirconia ceramic which results in a nanosized microstructure.

Addition of extra small particles at grain boundaries

If insoluble particles are dispersed in a ceramic matrix, grain growth will be retarded or even halted. These particles will exert blocking forces which will oppose grain boundary mobility, resulting in so-called “pinning” of grain boundaries as shown in Fig. 27. The blocking force is equal to the grain boundary migration force for a given grain size d (Zener equation according to Manohar *et al.*, 1998):

$$d_{\max} = 8r_i/3f_i \quad (1)$$

where r_i is the inclusion particle radius and f_i is the volume fraction of inclusions.

Eq. (1) demonstrates that the limiting grain size, $d_{\max}$ decreases as the volume fraction of second-phase particles is increased and their size is reduced.

[Science and Technology of Zirconia III, pub American Ceramic Society, Inc].

Fig. 28 shows the influence of insoluble particle content (zirconia) on matrix grain growth (alumina grains) for zirconia toughened alumina composites.

Bodisova *et al.* (2015) studied the effect of addition of zirconia as insoluble particles to alumina using the two step sintering (TSS) method. A first step was carried out at 1475°C followed by a second step at 1300°C which resulted in very limited grain growth compared with the composite conventionally sintered (CS) in one step at 1485–1500°C as shown in **Fig. 29**.

Fig. 30 shows the influence of insoluble particle content (nanosized silicon carbide) on alumina matrix grain growth in alumina-silicon carbide nanocomposites. The addition of only 1 vol% of nanometric silicon carbide into an alumina matrix allows the reduction of the matrix grain size and induces a change in fracture mode from intergranular to transgranular.

If the thermal expansion coefficient of the dispersed particles is lower than that of the matrix coefficient, dislocations can move under traction and form a substructure inside the matrix grains as shown in **Fig. 31** for alumina matrices containing nanoparticles of Mo or SiC. This usually results in a refinement of the matrix grain size with a consequent increase in flexural strength and this is shown for SiC reinforced tetragonal zirconia (TZP) in **Fig. 32**.

If the particle inclusions are slightly soluble in the matrix then Ostwald ripening may occur leading to a decrease in the number of small particles and growth of larger ones. According to Laplace's law, the atoms of a particle close to the inclusion-matrix interface are submitted to compressive forces which increase as the size of the inclusion decreases. The chemical potential of these atoms thus increases which enhances their solubility resulting in a flow of atoms from small particles to larger ones through a dissolution – diffusion – precipitation mechanism. This phenomenon was well illustrated in the case of zirconia-mullite composites obtained by reaction sintering from zircon and alumina in the presence of a small amount of MgO which favors formation of a small amount of liquid phase. The microstructural modifications of the composites as sintering temperatures increase (1500, 1550, and 1600°C) and dwelling times increase (0.5, 2, and 10 h) are clearly governed by Ostwald ripening as shown in **Fig. 33** (Leriche, 1986).

Summary

Ceramics are consolidated by heating powder compacts which results in their densification and elimination of porosity. The type of sintering mechanism directly influences the microstructural development of the ceramic. In all cases, simultaneously with densification, grain growth occurs. Therefore, it is crucial to know the impact of all process parameters on grain growth and densification mechanisms in order to control the final ceramic microstructure and the resulting properties.

The methods to control the microstructure of ceramics depend on the final product. Ceramic materials with 97%–98% densification level and normal grain growth can be processed by pressureless sintering. This involves appropriate thermal treatment conditions (temperature, duration) which favor lattice or grain boundary atomic diffusion enhancing densification and which limit surface diffusion responsible for grain growth. For systems which are susceptible to exaggerated grain growth, it is necessary to use special thermal regimes or schedules such as “fast firing”, “controlled rate sintering” or “microwave sintering” or to add very small amounts of other chemical species (grain growth inhibitors, submicron particles) in order to limit the grain growth by decreasing the grain boundary mobility. For liquid phase sintered ceramics, the microstructure can be controlled by adapting the intergranular phase viscosity and the seed content.

Several examples were presented showing the possibility of using different methods favoring grain growth reduction and achieving fully dense ceramic materials with nanosized microstructures.

Templated Grain Growth of Textured Ceramics

Introduction

Crystallographic texture has been shown to bestow unique properties on ceramics by taking advantage of intrinsic property anisotropy. Texture refers to either the preferred orientation of grains of a specific morphology (i.e., shape) or preferred crystallographic orientation. Morphological and crystal texture are often observed in the same material because the processing and grain growth processes leading to grain shape anisotropy in a microstructure are related to crystal anisotropy. In most textured systems strong preferred orientation is observed in only one crystallographic direction and is referred to as fiber texture. Biaxially-oriented materials with crystallographic orientation in two different axes are described as sheet-textured and have similar property anisotropy as a single crystal of the same composition. Sheet texture is typically observed in thin film ceramics in which a single crystal substrate directs oriented growth of the thin film. Sheet direction has only been achieved in thick film polycrystalline ceramics by the Rolling Assisted Biaxially Textured Substrates process (RABiTS) which uses a biaxially oriented metallic substrate to control oriented growth of the thick film (Goyal *et al.*, 2004). Low quality fiber texture in bulk ceramics with <20% texture is commonly observed when starting with particles with an aspect ratio of >2 and application of a shaping process in which unidirectional forces induce physical alignment of the anisometric particles. For example, dry pressing, hot pressing and spark plasma sintering often yield ceramics with weak texture as a result of the unidirectional action and associated particle reorientation of anisometric particles during the unidirectional pressing strain. Texture can also be slightly enhanced by grain rotation during hot pressing, or hot forging, of a dense ceramic but, unlike metals, the degree of texture is limited by very low plasticity in ceramics. In either case, the use of hot forming techniques, and the associated high cost, limits the use of such approaches to fabricate high quality textured ceramics in which the texture fraction is >90%.

Many powder and sol-gel processing techniques produce texture in ceramics. These processing methods are categorized in Fig. 1 by the driving force for particle alignment as either mechanical or electromagnetic (Messing *et al.*, 2017). It is noted that uniformly applied heating alone cannot create texture but does enhance pre-existing texture via preferential growth of aligned grains. However, thermal gradients, as used in directional solidification, can create texture during forming. Two general techniques have been developed in the past few decades to achieve ceramics with a high texture fraction (e.g., >95% texture fraction), including templated grain growth (TGG) (Seabaugh *et al.*, 1997) and reactive templated grain growth (RTGG) (Takeuchi *et al.*, 1999; Hong and Messing, 1999; Tani, 2006), and strong (7–14 T) magnetic field alignment (MA) of particles (Sakka and Suzuki, 2005; Suzuki *et al.*, 2006). Some of these processes can be used in tandem to achieve texture as indicated by the overlapping areas of diagram in Fig. 1 (Poterala *et al.*, 2013).

There is increasing interest in textured ceramics due to the development of the templated grain growth (TGG) process which enables access to high quality crystallographic texture. Templated grain growth (TGG) (Seabaugh *et al.*, 1997) is a process that takes advantage of the preferred growth of large grains in a dense microstructure by Ostwald ripening (i.e., large grains grow at the

Fig. 1 Electromagnetic, mechanical and thermal processing methods utilized to produce grain alignment in ceramic materials. Most commonly used processing methods are shown in bold. Fig. 2 A schematic of texture development by templated grain.

expense of smaller grains). In the TGG process, a minority of relatively larger, anisometric single crystal particles is mixed into a slurry of equiaxed, submicrometer particles. The template particles are oriented in the matrix powder by a shear-forming process like tape casting to align the template particles with a preferred crystallographic orientation (Fig. 2). Tape casting and extrusion are the most used processes for TGG but any process that imposes directional shear on the anisometrically-shaped particles results in alignment. Bulk ceramics are fabricated by stacking tape cast layers and laminating the stack. Heating the bulk composite of template particles dispersed in a fine particle matrix results in densification of the matrix powder around the template particles and then subsequent growth of the template particles by Ostwald ripening once the matrix reaches >95% density.

TGG has many advantages for fabricating oriented materials relative to single crystal growth processes. First, the technology is founded on the well-established industrial scale tape casting technology and is much less expensive than single crystal growth processes. Ceramics of much greater size and superior compositional uniformity are possible than with single crystal growth processes since the compositional uniformity of the powder processed ceramic is retained during sintering and templated grain growth. In contrast, single crystals grown from the melt undergo long range chemical segregation during crystal growth and thus only small portions of the single crystal are usable when exacting chemical composition is important for properties. Finally, textured ceramics are mechanically more robust than single crystals.

The templated grain growth (TGG) process is the focus of this chapter since it has been shown, since its invention in 1997, to yield high quality textured ceramics and because of the commercial interest in fabricating textured piezoelectric ceramics by TGG. The powder, template, process, sintering and grain growth conditions critical for fabrication of high-quality textured bulk ceramics with single crystal-like properties are presented. Progress over the last 20 years of textured ceramic properties of all types, and especially for textured piezoelectric ceramics, was recently reviewed (Messing *et al.*, 2017).

Templated Grain Growth

Several criteria need to be satisfied to obtain a textured material by TGG (Suvaci and Messing, 2000). Growth of the template particles depends on (1) the thermal stability and crystallographic properties of the template particles relative to the matrix material, and (2) maintaining favorable thermodynamic and kinetic conditions for template growth. The amount of growth, and thus the degree of texture, depends on the number, size and size distribution of the template particles relative to the matrix powder.

Template particles must satisfy several physical and crystallographic conditions to achieve high quality texture by TGG. First, templates must be anisometric, single crystals or nominally single crystal with a large aspect ratio (e.g., >10) to allow for alignment of a particle in a defined crystal axis direction during forming. Since most available template particles are tabular in shape, tape casting is the most common technique used for producing textured ceramics by TGG. Acicular particles can be well-aligned during tape casting by using a gated doctor blade (Messing *et al.*, 2004). Extrusion is also used for TGG when acicular template particles, such as silicon nitride and mullite, are available. Alignment of tabular particles by extrusion depends on the aspect ratio of the extrusion die; circular dies lead to coaxial orientation.

Walton *et al.* (2019) showed that the magnitude of torque on the template particle during tape casting significantly affects the quality of anisometric particle orientation. Orientation of anisotropic particles during tape casting is related to the velocity profile in the slurry and the resistance to motion of the viscous slurry as the slurry passes under the doctor blade (Fig. 3). The velocity profile under the doctor blade can be modeled as a combination of pressure-driven flow and drag driven flow (Fig. 3(b)), and is primarily dominated by drag driven flow under typical tape casting conditions (e.g., 2–50 mm s^{−1} casting velocity, 0.25–2 mm gap height, 2–30 mm reservoir height).

The shear rate at any point in the velocity profile is calculated by taking the slope of the velocity profile. If the rheological behavior of the slurry is known, the gradient in the shear stress under the doctor blade can be determined. Furthermore, the shear stress (τ) acting on the surface of the template particle at any position under the doctor blade can be calculated for a known shear rate ($\dot{\gamma}$) and the experimentally determined dynamic viscosity (η_D) using Eq. (1).

$$\eta = \dot{\gamma} \eta_D \quad (1)$$

The gradient in shear stress across the major axis of the template particle (i.e., diameter or length) generates a torque that rotates and aligns the template particle parallel to the velocity profile. Eq. (2) is a 1D torque approximation, where M is the torque, δ_y is the projection height of the particle, and $\tau_{(y + \delta_y)}$ and τ_y are the shear stress values on either end of the particle.

$$M = (\tau_{(y + \delta_y)} - \tau_y) \delta_y \quad (2)$$

When the face of a platelet particle is oriented perpendicular to the casting direction, the projection height (δ_y) is at a maximum at the platelet or fiber major dimension. As the platelet angle relative to the casting direction approaches 0° , the projection height approaches the thickness of the platelet (approximately zero as platelet thickness $\ll$ platelet diameter). When perfectly aligned, the diameter of the platelet or fiber length is parallel to the direction of the applied shear. The dynamic viscosity (resistance to shear flow) of the slurry creates resistance to the template particle changing orientation, and thus the magnitude of the viscous resistance depends on the dynamic viscosity, rotational velocity of the platelet, and the surface area of the template. Particle alignment under any set of tape casting conditions therefore depends on how the magnitude of torque balances with the viscous resistance of the slurry. If the torque generated during casting is sufficient to overcome the viscous resistance and rotate the particle while it is under the doctor blade, then the template particles will become well aligned. After casting the templates will remain well aligned, since the aligned particles must overcome the rest viscosity (i.e., zero shear rate) of the slurry to rotate further. Thus, changes in casting speed, rheology and casting height, and particle aspect ratio can dramatically affect particle alignment by virtue of the torque acting on the particle during shear.

As indicated by Eq. (2), the higher the aspect ratio of the template particle, the easier it is to align individual template particles. Fig. 4 shows how the quality of texture depends on the aspect ratio of the tabular particle aligned by tape casting. In this case the quality of orientation is quantified using an x-ray rocking curve to measure the orientation distribution of the grains in the final sintered ceramic. The full width at half maximum (FWHM) of the distribution function is a measure of orientation quality with a small value of FWHM indicating a high degree of platelet orientation. Although shape anisotropy is a necessary characteristic for template orientation during shear forming, particle shape is not necessary if crystallographic alignment is accomplished using a high field magnet (i.e., 7–14 T) (Sakka and Suzuki, 2005). Poterala and Messing combined TGG and a 3 T magnet to align templates during slip casting to texture PMN-PT (Poterala *et al.*, 2013).

The template particle must be nominally single crystal and satisfy conditions for epitaxial growth during the TGG process. For example, tabular, single crystal alumina template particles with (0001) basal surfaces are used to template [0001]-textured alumina by TGG. This is a classic case of homoepitaxy in which there is no lattice parameter misfit between template and matrix, and thus homoepitaxial growth of the template particle readily occurs. Tabular (001)_c BaTiO₃ (BT) particles are used as heteroepitaxial templates for producing [001] textured lead-based piezoelectrics like 0.675Pb(Mg_{1/3}Nb_{2/3})O₃–0.325PbTiO₃ (PMN-PT) and Pb(In_{1/2}Nb_{1/2})O₃–Pb(Mg_{1/3}Nb_{2/3})O₃–PbTiO₃ (PIN-PMN-PT) since it is possible to synthesize high aspect ratio tabular BT particles by a molten salt process. Also, the lattice parameter mismatch with the matrix is <2%. For heteroepitaxial growth the template particles must have a similar crystal structure and <15% lattice parameter matching. When templates do not have the same composition as the matrix material they can either dissolve in the matrix after TGG, as happens in the case of SrTiO₃-templated PMN-PT (Kwon *et al.*, 2005), or, as in the case of textured lead-based and non-lead based perovskites, the BT templates remain at the core of the templated grains.

When the matrix is a chemical precursor (e.g., sol gel) or mixture of powders to the final ceramic phase, the template particles can act as nucleation sites (see Calcination and Phase Transformations) and seed the solid state reaction or phase transformation of the matrix. This process is referred to as Reactive TGG (RTGG) because of the dual role of the templates (Takeuchi *et al.*, 1999; Hong and Messing, 1999; Yilmaz *et al.*, 2003). It is important to note that the material seeded by the template has the same crystallographic orientation as the template and thus the effective volume of oriented material after phase formation and prior to densification can be significantly greater than with TGG. The RTGG process is useful when the template is unstable at high temperature. By acting as a seed for the phase transformation the oriented material formed on the surfaces acts as the effective template once the ceramic is densified. Tani reported a unique means to form the template particle by an *in situ* topochemical process. (Fig. 5).

The degree of texture is directly related to the amount of growth on the template grains. The grain size of the textured ceramic of a fully textured can be calculated by assuming the rectangular templates are distributed on a rectangular lattice such that the surface to surface distance of the templates is the same in all directions.

The final grain size is the same as the spacing of templates (x_t), which depends on the number frequency of the templates per unit volume (f_t) according to Eq. (3).

$$x_t = \left(\frac{6}{\pi f_t} \right)^{1/3} \quad (3)$$

Templated Grain Growth

Reactive Templated Grain Growth

Fig. 5 Schematic of the TGG and reactive TGG process. The *in situ* topochemical conversion texturing process (b) The oriented seeding of a phase transformation texturing process. Adapted from (c) Messing, G.L., Poterala, S., Chang, Y., *et al.*, 2017. Texture-engineered ceramics – Property enhancements through crystallographic tailoring. J. Mater. Res. 32, 3219–3241.

where

$$f_t = \frac{N_t}{V_{tot}} = \frac{6m_t}{\pi\rho_o V_{tot}} \sum_{i=1}^n \frac{wf_i}{d_i^3} \quad (4)$$

and N_t is the number of templates, V_{tot} is the total volume of the powder, m_t is the weight of the templates added, ρ_o is the theoretical density of the template material, and d_i is the template size for a given weight fraction, wf_i .

Fig. 6 shows how grain size depends on the template size and the number of templates per unit volume (f_t). If 5 vol% of $10 \mu\text{m} \times 10 \mu\text{m} \times 1 \mu\text{m}$ templates are added, then $< 10 \mu\text{m}$ growth is needed on each templated side to achieve 100% texture and the grain size of the textured ceramic is nominally $20 \mu\text{m}$. For smaller templates even less growth is required since the number fraction of particles scales with template size⁻³. However, template size cannot be decreased too much without reducing shear alignment and the thermodynamics of growth. On the other hand, very small concentrations of large template particles require a significant amount of growth to obtain 100% texture. Finally, increasing the template loading to $> 10 \text{ vol}\%$ leads to a degradation of the quality of the orientation as evidenced by broadening of the orientation distribution function (i.e., increase in FWHM).

After orienting the template particles in the matrix, the formed part must be densified before the templated grains can grow. When equiaxed powders are sintered, pores on the grain boundaries retard grain growth until about 92% density, at which point matrix grains undergo normal grain growth. Likewise, there is not significant template growth until $> 95\%$ density in most systems (Suvaci and Messing, 2000). Fig. 7 shows the progress of [001] texture evolution in CuO-doped PIN-PMN-PT templated on tabular BaTiO₃ template particles as a function of sintered density (Chang *et al.*, 2017). Only when the ceramics are $> 96\%$ density is there substantial oriented templated grain growth on the BT templates and 95% texture is achieved. Note that the grains have a cuboidal shape as a result of the isotropic growth of the pseudocubic PIN-PMN-PT formed. This example illustrates that anisotropic, or so-called exaggerated, grain growth is not necessary for TGG.

Fig. 6 Calculated templated grain size as a function of template size and concentration for a 100% textured material.

Fig. 7 Texture fraction (F_{001}) of [001] textured 0.28PIN-0.40PMN-0.32PT ceramics (a) as a function of relative density for different CuO contents (x) and (b) cross-sectional SEM micrographs of templated 0.28PIN-0.40PMN-0.32PT ceramics with no dopant and 0.125% CuO dopant. Adapted from Chang, Y., Watson, B., Walton, *et al.*, 2017. Enhanced texture evolution and piezoelectric properties in CuO-doped $\text{Pb}(\text{In}_{1/2}\text{Nb}_{1/2})\text{O}_3\text{-Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3$ grain-oriented ceramics. *App. Phys. Lett.* 111, 232901–232905.

Fig. 8 Micrographs of cross-sections of (a) a templated alumina green body and (b) TGG alumina doped with 2% CaO/SiO₂ dopant after heating at 1550°C for 90 min (c) Sintered density of textured alumina vs. template loading for samples with no dopant, 0.14% dopant, and 2% dopant after heating at 1550°C for 90 min. Adapted from Pavlacka, R.L., Messing, G.L., 2010. Processing and mechanical response of highly textured Al₂O₃. *J. Eur. Ceram Soc.* 30, 2917–2925.

Fig. 8(a) shows a cross-sectional view of alumina with 5 vol% tabular alumina particles aligned in the matrix and the textured alumina formed when a 2% wt% dopant is added and sintered at 1550°C for 90 min (**Fig. 8(b)**). **Fig. 8(c)** demonstrates the effect of adding template concentrations of 1–15 vol% and 0–2 vol% liquid phase-forming dopants on densification. As the template concentration increases, the sintered density decreases to 94% for 5 vol% templates and 91% when 15 vol% templates are added. With no dopant, alumina densifies by a solid-state mechanism and thus the large alumina template particles impose constraining stresses in the sintering system and also decrease densification by forming a percolating network of template particles in the x-y plane of the ceramic. To alleviate the stresses from the large template particles, a dopant that forms a liquid during sintering is added. **Fig. 8(b)** shows the liquid formed during sintering reduces the constraining stresses, and as a result 95% dense textured alumina can be attained with 15 vol% template particles. To avoid the adverse effects of template particles on densification, a liquid phase is used in almost all cases of TGG. Besides assisting densification, the liquid phase also increases the kinetics of template growth. It is important to note that dopant chemistry should be designed to avoid having a negative impact on the properties of the textured ceramic.

The calcium silicate dopant was specifically chosen for textured alumina to facilitate anisotropic growth on the templated grains. Rapid growth was perpendicular to the basal plane and stops once the growing grains ‘impinge’ and finer grains no longer exist and thus the thermodynamic driving force for growth in that direction is nearly zero. A slower growth process perpendicular to the fast growth direction continues until the matrix is completely consumed or the matrix grains coarsen to the point where the thermodynamic driving force is eliminated. TGG in the absence of a liquid is also possible but issues of constrained densification and slower solid-state diffusion processes, as noted above, limit the viability of solid-state diffusion driven TGG.

Most TGG systems use a liquid phase to reduce constraining stresses on sintering due to the large particles, and to increase the kinetics of template growth. The driving force for template growth in the presence of a liquid is provided by the solubility difference between the matrix grains and the template material in the surrounding liquid (S_m and S_t , respectively). Supersaturation arises from the curvature of the matrix grains relative to the growing template surface and thus underscores the importance of a matrix with a fine grain size after the sintering stage of TGG (Seabaugh *et al.*, 2000). The relative degree of supersaturation can be described by the Gibbs-Thomson equation. Thus, for a matrix of average grain size r and a growing template surface of radius R_t

$$\Delta S = \frac{2S_o M}{\rho RT} \left(\frac{\sigma_m}{r} - \frac{\sigma_t}{R_t} \right) \quad (5)$$

where σ_m and σ_t are the surface energies of the matrix grains (average) and the growing surface of the template grains, respectively, S_o is the intrinsic solubility of alumina in the liquid phase during growth and M is the molar volume of alumina. For tabular particles the smaller dimension surface is most important for initial growth by TGG since that is the highest energy surface for the template particle.

In anisotropic crystal systems the growth of highly packed atomic planes is relatively faster because such surfaces have a higher surface energy. This growth anisotropy means that the dimension (e.g., thickness or diameter of whiskers) of the growing surface must be greater than the matrix grain size to maintain a thermodynamic advantage for growth. As shown for the growth of single

crystals by solid-state conversion, matrix grain growth can reduce the thermodynamic driving force enough that template growth stops (Rehrig *et al.*, 2000). Thus, a greater size difference between the matrix grains and the templates result in a higher driving force for template growth. It has been shown that the minimum size ratio to sustain template growth is ~ 1.5 , which is consistent with critical size criteria for exaggerated grain growth attributed to Hillert (Hillert, 1965). Since the matrix grains also begin to grow during TGG once the matrix achieves $>92\%$, then heating conditions may need to be tailored to limit excessive matrix grain growth so as to preserve the size advantage of the template relative to the matrix grains. The kinetics of template growth is well explained by either interface reaction-control or diffusion-controlled models. As shown for alumina and PMN-PT, initial growth is diffusion-controlled but growth mechanism changes to interface reaction control once the grains become faceted.

Summary

Templated grain growth is an excellent, relatively low-cost process for producing high quality textured materials with $>95\%$ texture fraction and a full width at half maximum in a rocking curve of $<10^\circ$. Fiber and biaxial textured ceramics require template particles of uniform size and shape, and more control over their distribution during forming. While this chapter describes the application of TGG to ceramics it is apparent that the process can be applied to a variety of inorganic material systems, and may even have some possibilities for organic systems.

Functionally Graded Ceramics

Omer Van der Biest, Department of Materials Engineering, KU Leuven, Leuven, Belgium
Achim Neubrand, Fraunhofer Institute for Mechanics of Materials, Freiburg, Germany

© 2021 Elsevier Inc. All rights reserved.

Introduction

Functionally graded materials (FGMs) are multifunctional materials, which contain a gradual spatial variation in composition and/or microstructure for the specific purpose of controlling variations in structural or functional properties. An important aspect is that the spatial distribution of microstructure and/or composition is tailored and quantitatively controlled in order to achieve an improvement in properties of the final component with respect to a homogeneous material (Mortensen and Suresh, 1995; Neubrand and Rödel, 1997; Gasik, 1995).

The concept of FGMs derives from the consideration that the service conditions and required materials performance vary with the location in a large number of components. Consider for example a turbine blade, which must withstand high non-stationary heat fluxes and centrifugal acceleration. An ideal structure for this application would consist of a tough metal core and a corrosion and heat resistant ceramic at the hot surface of the blade. If the ceramic is directly bonded to the metal, spalling may occur during thermal cycling because of the high thermal stresses at the interface. A graded material with a smooth transition from the ceramic surface to the metal core can reduce the thermo-mechanical stress concentration at the interface, and thus has better performance. There are many other applications where the requirement for properties cannot be attained by a single material (Neubrand and Rödel, 1997). In all these cases, graded materials offer the possibility to combine two materials properties, avoiding most of the disadvantages of a bi-material. Fundamental and applied research in the past has clearly shown that the introduction of compositional step and profile gradients in FGMs can be a benefit on many accounts (Suresh and Mortensen, 1997; Munz *et al.*, 1998; Bao and Cai, 1997).

FGMs are commonly found in nature with examples such as the varying spongy trabecular structures of bone (Wegst *et al.*, 2014) or local tissue variation in seashells and plants e.g., Norway spruce (Eder *et al.*, 2009) and bamboo (Habibi *et al.*, 2015).

There are also examples of early synthetic materials taking advantage of property gradients such as case-hardened steels in which a hard surface is combined with a tough interior. In fact, this idea has been exploited for hundreds of years in the iron or steel production (Gasik, 1995). Although it is not difficult to find some examples in the history of our civilization using the idea of graded materials, as a systematic engineering approach it is far from being the norm. Instead, current engineering practice generally involves the design of a part using one of a large number of generally mass-produced uniform materials. When a structure requires vastly different materials, different uniform materials are joined along sharp boundaries using a variety of joining or coating methods. The task of the materials engineer is defined as seeking to improve materials, while the task of the structural part designer is using the handbooks of available materials. With the innovative FGM concept, component design and fabrication are based not on a list of existing materials but on a choice of available basic material ingredients and material processes, combined with three-dimensional mechanical analysis of graded structures. These two engineering disciplines are combined to synergistically design both the component and its processing. Here lies a second definition of the functionally graded materials concept, as an approach in engineering rather than a physical entity (Mortensen and Suresh, 1995). When additive manufacturing processes are used to fabricate a part, the manufacturing must start from a full 3D design of the part from which the software is generated to steer the machine that usually will build up the part layer by layer. In the most advanced forms of these new technologies, the file will also need information on the local material combination that has to be generated by the machine at a particular location.

Niino *et al.* (1987) first proposed the concept of manufacturing a thermally graded metal-to-ceramic phase for a thermal barrier application. An FGM was seen as an “inhomogeneous composite”, in which the material’s mechanical, physical, and chemical properties change continuously, and which have no discontinuities within the material. FGMs have been intensively investigated since then.

Meanwhile it has become common practice to use the term FGM not only for composites, as defined above, but also for all materials with a macroscopic property gradient. Thus, materials containing only one phase such as graded glasses or graded single crystals are also FGMs. In such materials the spatial property variation is caused by a gradient in chemical composition. The vast majority of FGMs are composite materials with a macroscopic micro-structural gradient i.e., with more than one phase present. For example, the composite may contain a spatially varying volume fraction of one of the phases (Fig. 1(a)). On the other hand, a composition gradient is not inherent to all FGMs. Microstructural gradients may also be obtained in composites by changing the shape (Fig. 1(b)), orientation (Fig. 1(c)), or size (Fig. 1(d)) of the dispersed phase.

There are a number of possibilities to classify graded materials (Cherradi *et al.*, 1994; Neubrand and Rödel, 1997):

- (1) According to the relative extension of the gradient, i.e., to what extent the gradient is distributed across a component. In a bulk FGM the property variation extends over a large part of the component, whereas in a graded coating or joint it is restricted to a volume near the surface of the material or to a restricted interfacial region.
- (2) According to the material classes which the graded component combines, e.g., metal/ceramic, polymer/ceramic, metal/metal, ceramic/ceramic, etc. In this text we will focus on FGM in which one of the materials/phases is a ceramic compound.

Fig. 1 Different types of functionally graded composites. Gradient of: (a) fraction, (b) shape, (c) orientation, and (d) size of material. Reproduced from Neubrand, A., 2001. Functionally graded materials. In: Jürgen Buschow, K.H., Cahn, R.W., Flemings, M.C., *et al.* (Eds.), *Encyclopedia of Materials: Science and Technology*. Amsterdam: Elsevier, pp. 3407–3413, (ISBN: 0-08-043152-6).

Properly designed property gradients in materials lead to a performance that cannot be achieved with a homogeneous material or by the joining of two different materials. The gradient can thus be regarded as an additional material design parameter which may be adapted and optimized to meet the requirements of a particular application. This leads to the unusual situation that the performance of the material is strongly influenced by geometric factors such as the shape of the material, and the extension and profile of the property gradient. Thus, a gradient material cannot be fully characterized by materials constants only, and already comprises certain aspects of the design of a component. Hence material selection and component design are closely intertwined and one cannot be divorced from the other. The gradient composition in FGMs results not only in a spatial variation in properties but will also generate residual stresses, which will affect the mechanical properties. One of the potential advantages of FG components is the positive influence of compressive residual surface stresses on the strength and wear resistance. A correct design of the gradient for an optimal distribution of the residual stresses is therefore important, as discussed later.

The present summary builds on and updates reviews that both authors have been involved in during the early years of FGM research (Neubrand, 2001; Anné *et al.*, 2006). Due to the context of this chapter the focus will be on FGM systems involving ceramics and glasses, i.e., functionally graded ceramics and glasses. Examples involving other materials may occasionally be referred to in order to inspire further research on ceramic containing FGMs. It is worth mentioning also that because of the large differences in stiffness between ceramics on one side and metals and polymers on the other side, functionally graded transitions between these classes of materials have been widely investigated.

As research on FGM has matured, FGMs are becoming of greater interest for numerous applications, including aerospace engineering, nuclear power generation, sensors, biomedical implants, optoelectronic devices, and energy absorption systems. Some FGM applications involving ceramics will be discussed at the end of this chapter.

Theoretical Research

The steepness of the gradient in an FGM can be described by the use of a transition function $f(x,y,z)$. In many practical cases the compositional variation will be restricted to one coordinate, say z , and different gradients can then be described by a so-called transition function of the type:

$$f(z) = (z/d)^p \quad (1)$$

where f denotes the composition or volume fraction of one of the phases, d is the thickness of the graded region, and p is the so-called gradation exponent.

Most of the theoretical research on FGMs has been devoted to their macroscopic mechanical and thermal behavior and there has been considerable progress in understanding the effects of gradients on the stress distribution within such materials (reviewed by Suresh and Mortensen, 1998). A gradation of the elastic modulus and/or of the thermal expansion coefficient changes the stress distribution in a component when it is mechanically or thermally loaded. A simple but illustrative example is a three-layered beam of infinite length in the x -direction, and unit width in the z -direction. In the y -direction it consists of two homogeneous layers of thickness h_1 and h_2 and a graded interlayer of thickness g (Fig. 2). For this simple geometry the stresses inside the beam can be conveniently calculated using classical continuum mechanics. It is assumed that plane stress conditions prevail in the center of the

beam. If the beam is subjected to a uniform temperature change from a stress-free temperature, a strain gradient in the thickness direction y will evolve due to the difference in thermal expansion of the two materials and the beam will bend. The only nonzero stress in the center of the beam is $\sigma_{xx}(y)$. The stress distribution $\sigma_{xx}(y)$ for a Cu/Al₂O₃ beam of 5 mm thickness after a uniform temperature change of 100K is shown in Fig. 3. In the case of a simple bimaterial ($g = 0$, $h_1 = h_2 = 2.5$ mm) a large stress jump with high compressive stresses in the Al₂O₃ and high tensile stresses in the copper is predicted near the interface. If a layer that possesses a linear variation of thermal expansion coefficient and elastic modulus from copper to Al₂O₃ is introduced in the central part of the beam ($h_1 = h_2 = 1$ mm, $g = 3$ mm, exponent p of the transition function = 1), the stresses $\sigma_{xx}(y)$ will be substantially reduced and the abrupt change in sign of the stress disappears. Instead, a gradual transition from tensile to compressive stress is observed and the stress becomes zero in the center of the beam. If desired, the exact location y , where $\sigma_{xx}(y)$ vanishes can be shifted to a different position by choosing an appropriate transition function. If the linear gradation of the thermal expansion coefficient extends over the whole plate thickness ($h_1 = h_2 = 0$, $g = 5$ mm), the thermal stresses will even vanish completely, although differences in thermal strains across the bar will always be present and the bar will bend after a uniform temperature change of 100K. On the other hand, if the graded layer is thin compared to the homogeneous layers ($g < h_1 + h_2$) the force balance inside the whole beam will not be affected and the stress reduction in the nongraded part will be negligible.

It should be pointed out that a stress reduction in bimaterials is not a general feature of FGMs. For arbitrary geometry and loading situation, the gradient will not always lead to a decrease in stress. However, a properly chosen gradient in the elastic properties can aid in redistributing stresses in a favorable manner. This can be an important feature in situations where the size or shape of a component is restricted.

So far, only stresses in the interior of an FGM have been considered. There is another important effect of the gradient on the stresses at the free edge of the beam, in particular at the locations where the interface intersects the free boundaries. Assuming elastic material behavior, the stresses become singular (infinite) at these locations. A similar stress singularity for the stress σ_y and the shear stress τ_{xy} is predicted at an elliptical pore located at the interface of dissimilar materials (Yang *et al.*, 1997). The stress concentrations at the free edges or pores are sites where the nucleation of critical cracks (leading to delamination) is likely to occur. If a graded zone with continuously varying mechanical properties is introduced, the stresses at the free edge of the interface become finite (Yang, 1998). It was also demonstrated that the introduction of a gradient leads to finite values of σ_y and zero shear stresses τ_{xy} at a pore located at an interface. It is therefore expected that delamination cracking in bimaterial joints or coatings can

Fig. 4 Overview of conventional manufacturing methods (CM) for FGM materials. be substantially reduced or suppressed by the introduction of a property gradient. This rather universal feature of FGM's is particularly relevant for graded ceramics where stress concentrations or singularities cannot be relaxed by plastic flow.

In the above, only the effect of a gradient in elastic and thermal properties on the stress distribution in a crack-free material was discussed. However, a gradient will not only affect crack initiation, but also the mechanical energy release rate of an existing crack. Fracture mechanics calculations show that an edge crack propagating along the interface of a homogeneous coating possesses a higher mechanical energy release rate compared to a crack in a graded coating (Erdogan, 1995). Furthermore, a suitable local variation of fracture toughness and subcritical crack growth behavior can improve the fatigue life of a component considerably. An example is a titanium alloy with gradual transition from a fully aged, brittle, high-strength surface to a ductile, low-strength interior, which leads to a considerably improved high-cycle fatigue strength (Berg and Wagner, 1999).

Processing Techniques for FGM

A large part of the research work on FGMs has been dedicated to processing and a large number of production methods have been developed (reviewed by Suresh and Mortensen, 1998; Neubrand and Rödel, 1997; Kieback *et al.*, 2003). Initially, most of the processes for FGM production were based on a variation of conventional manufacturing methods (CM) which are already well established. Later on, around 2010, additive manufacturing (AM) methods have been explored and have given the research field of FGM a new boost. AM will be discussed in detail below. Fig. 4 (Naebe and Shirvanimoghaddam, 2016) shows an overview of the CM methods. Which of these production methods is most suitable depends mainly on the material combination, type of transition function required, and geometry of the desired component.

When selecting the processing method, the property difference of the two constituent phases of the FGM is of primary importance. In a compositional FGM for example, the difference in heat resistance between the two phases is a key factor. If the two phases have a significantly different melting point, like in ceramic/metal FGMs, the composition gradient can be formed by producing a porosity gradient preform of the refractory phase subsequently infiltrated by the molten metallic phase to get a dense final product. If the two phases have a similar melting point, infiltration cannot be used because the skeleton cannot keep its strength during infiltration. The dimension and geometry of the FGM has to be considered as well. For instance, it is feasible to produce FGMs in many material systems with thermal spraying technologies. Their low efficiency however makes them useless for the production of three-dimensional bulk FGMs.

Conventional manufacturing methods (CM) can be broadly classified into two fields: bulk processing methods such as sedimentation, powder stacking, and centrifugal casting, and coating methods (Fig. 4). Table 1 presents a summary of various fabrication techniques for FGMs. Some studies describe bulk processes. Other processes are only suitable for the coating of surfaces for instance by slurry dipping, chemical solution deposition, and chemical vapor deposition. Some methods sit in between these two categories, such as thermal spraying, laser cladding, and electrophoretic deposition. However, even with one of the most widely accepted and applied CM methods, that is, the thermally sprayed coatings, limitations are obvious because they can only

construct simple FGM objects with uncomplicated gradient structures. Methods that are capable of accommodating a gradation step include powder processing, thermal spraying, melt processing, and coating processes. These will now be reviewed in turn.

Powder Processing

Shaping and consolidation processes for FGMs

For the fabrication of bulk FGMs, powder processing is most economic and suitable for mass production. The processes used for powdered ceramics are in principle the same as those used for powdered metals i.e., powder metallurgy (PM) processes. However, some ceramics, in particular non-oxides can be produced from the so-called pre-ceramic polymers. In order to produce a FGM by conventional powder processing, a green body with the desired gradient in phase volume fraction is first fabricated. After shaping and consolidation, this green body has to be densified by sintering.

The gradation methods can be divided into two groups: dry and wet processes (Fig. 5, Neubrand and Rödel, 1997). Dry processes are fast, but in general only allow to generate step-graded profiles. In wet processing, a drying step is required for the removal of the liquid but continuous mixing is facilitated and smoother continuous gradients may be produced. Furthermore, transport processes occurring in suspensions, e.g., sedimentation and electrophoresis, may be used to produce gradients at low cost. The main challenge associated with powder processing is frequently the densification of the graded powder compact. Sintering rates differ with position and uneven shrinkage may lead to warping and cracking, unless sophisticated sintering techniques are employed.

A widely used technique for ceramic/ceramic gradient materials is sequential slip casting where slips of different compositions are cast one after and over another (Requenna *et al.*, 1993). By using a premixing system, the casting composition can be tailored continuously (Chu *et al.*, 1993).

In a process called wet spraying (Schindler *et al.*, 1998), suspensions of two powders are created, and mixtures of variable composition are sprayed on a heated substrate in a computer-controlled process. After forming, the green body is removed from the substrate, for bulk FGMs, or bonded with the substrate, for FGM foils. Centrifugal casting (Fukui *et al.*, 1994; Watanabe *et al.*, 1998) is another FGM consolidation method using suspension mixing to realize the gradient. When suspensions of two powders of different density or different grain size are mixed and injected into a cylindrical cavity, which is rotating at high speed, the centrifugal forces cause a compositional or porosity gradient in the growing powder compact in the radial direction. Before stopping the rotation, wax is injected into the system to bind the powders in order to increase the green strength for body

Fig. 5 Conventional manufacturing (CM) via powder processing, also called powder metallurgy (PM) for bulk FGM (after Neubrand and Rödel, 1997). Fig. 6 Electrophoretic deposition (EPD) process for FGM materials. Reproduced from Anné, G., Vleugels, J., Van der Biest, O., 2006. Functionally graded ceramics. In: Low, I.M. (Ed.), *Ceramic-Matrix Composites: Microstructure, Properties and Applications*. Cambridge: Woodhead Publishing Limited. pp. 575–596.

handling. The porous FGMs with a gradient distribution in porosity can be used as a pre-form for filters, or for ceramic membranes. A process similar to centrifugal casting is gravitational sedimentation (Bernhardt *et al.*, 1999). Centrifugal casting can only be used for cylindrically shaped parts, whereas gravitational sedimentation is suitable for flat FGMs.

Among the different colloidal processing techniques, electrophoretic deposition (EPD) is a very promising method (Put *et al.*, 2003a,b, 2002; Vleugels *et al.*, 2003; Anné *et al.*, 2004) because it is a fairly rapid, low-cost process for the fabrication of ceramic coatings, monoliths, composites, laminates and functionally graded materials varying in thickness from a few nanometers to centimeters (Van Der Biest and Vandeperre, 1999). Electrophoretic deposition is a two-step process (Fig. 6). In a first step, particles having acquired an electric charge in the liquid in which they are suspended are forced to move towards one of the electrodes by applying an electric field to the suspension (electrophoresis). In a second step (deposition), the particles collect at one of the

electrodes and form a coherent deposit on it. The deposit takes the shape imposed by this electrode. After drying and removal from the electrode, a shaped green ceramic body is obtained. Firing this green body then results in a ceramic component. Gradient materials can be obtained since the composition of the next powder layer that deposits is determined by the composition of the suspension at that moment (Fig. 6). Judiciously adapting the powder concentration in the suspension allows to generate a well-controlled gradient profile in a continuous shaping step. The process is not material specific, since a wide variety of materials including metal powders, ceramics, glasses, and polymers have already been deposited (Van Der Biest and Vandeperre, 1999). In general, the only shape limitation is the feasibility to remove the deposit from the electrode after deposition.

Continuously graded materials in the $\text{Al}_2\text{O}_3/\text{ZrO}_2$ (Vleugels *et al.*, 2003c), ZrO_2/WC (Put *et al.*, 2002), and WC/Co (Put *et al.*, 2001) system have been explored by means of EPD. A prerequisite for successful production of FGM materials by means of EPD is

Cambridge: Woodhead Publishing Limited. pp. 575–596.

a full control of the kinetics of the process. Kinetic models have therefore been developed for processing an FGM in a multi-component system by means of EPD (Put *et al.*, 2003a). As an example, the composition profile (Fig. 7) and the microstructure (Fig. 8) of an $\text{Al}_2\text{O}_3/\text{ZrO}_2$ FG disk (Vleugels *et al.*, 2003) with a homogeneous composite core (75 vol% Al_2O_3), a pure Al_2O_3 surface layer on one side and a homogeneous composite (90 vol% Al_2O_3) on the other side, and intermediate symmetrically profiled graded layers is presented. As will be explained below, a convex alumina gradient profile is suggested to result in the highest compressive stress in the alumina outer layers and the lowest tensile stresses in the core of the disk. The ZrO_2 (white) and Al_2O_3 (gray) phases can be clearly differentiated in the microstructure. The ZrO_2 phase is well dispersed in the Al_2O_3 matrix in the gradient parts and in the core of the FGM.

Densification of FGM powder compacts

Almost all ceramic/ceramic bulk FGMs are densified by conventional pressureless sintering (Wu *et al.*, 1996; Marple and Boulanger, 1994; Cichocki and Trumble, 1998) or hot pressing (Kawai and Wacamatsu, 1995; Vanmeensel *et al.*, 2004), depending on the sintering properties of the two components. In metal/ceramic FGMs with a continuous metal phase and a discontinuous ceramic phase, the sintering rates are controlled by the densification of the metal phase and such FGMs can be densified by conventional sintering methods (Neubrand and Rödel, 1997). In most FGMs where a high ceramic phase content is envisaged however, some special approaches have to be considered for full densification. The major problem when sintering FGMs are the sintering rates which may differ by orders of magnitude depending on composition leading to cracking or warping of the compacts. Numerous efforts to counterbalance unequal sintering activity have been undertaken (Miyamoto *et al.*, 1999), including adaptation of particle size of the powder components in such a way that the sintering rate becomes similar over a wide range of temperature, and addition of a sintering aid to the more refractory component to increase its sintering rate. Local sintering rates can also be equalized by sintering in a temperature gradient which can be produced by laser surface heating or plasma-activated sintering in a stepped or tapered die (Tokita, 2003). Hot pressing is also an efficient means to prevent deformation. It should be born in mind that when sintering succeeds and a near full density FGM material is obtained at the sintering temperature, thermal stresses may originate during cooling due to differences in thermal expansion coefficients between the phases. The inability of the phases to accommodate these stresses by plastic deformation may lead to permanent residual stresses in the microstructure, which when they exceed the local strength of the material, will lead to cracks. Hence, due to excessive thermal residual stresses, cracks and other defects may often be observed in the final FGM component unless properly manufactured.

Fig. 9 shows typical cracks observed in symmetrically graded $\text{Al}_2\text{O}_3/\text{ZrO}_2$ (b) and WC-Co-TiC (c) disks, shaped by electrophoretic deposition and densified by pressureless sintering. Transverse cracks were observed in the ZrO_2 -rich core of the sintered symmetric TZP/ Al_2O_3 disks. The crack propagation however stopped in the outer pure Al_2O_3 layer indicating that the in-plane tensile stress is located in the center of the disks, which should be lowered. Transverse cracks were also observed perpendicularly to the surface at both outer TiC-containing sides in symmetrical WC-Co/TiC FGM disks (see Fig. 9(c)). In this case, the outer surface is facing higher tensile stresses during sintering.

Hillman *et al.* (1996) observed similar defects in symmetrical laminates with $\text{Al}_2\text{O}_3/\text{ZrO}_2$ layers at the surface and a ZrO_2 central layer. Cai *et al.* (1997a,b) discussed the embryonic stage of a sinter crack as observed in Fig. 9(b), and found regions of low density and cavitation defects in $\text{Al}_2\text{O}_3/\text{ZrO}_2/\text{Al}_2\text{O}_3$ laminates. These defects are most susceptible to residual tensile stresses during cooling in the core, due to the higher coefficient of thermal expansion (CTE) of zirconia. These regions of lower density (pores) must have formed as a result of the tensile stress that develops during the differential shrinkage during densification between the Al_2O_3 and the $\text{Al}_2\text{O}_3/\text{ZrO}_2$ layers. The pores then act as pre-existing flaws for the generation of thermal expansion mismatch cracks during cooling via linkage of the pores and cavitation defects.

Elimination of the transverse cracks can be accomplished by decreasing the overall shrinkage of the composites. This is done by either decreasing the compositional difference between the different layers (Cai *et al.*, 1997a,b), or by adjusting the green density of

the different layers (Novak *et al.*, 2005). Another possibility is to decrease the cooling and heating rate during sintering (Cai *et al.*, 1997b). The mismatch stresses during the heating cycle are decreased by the viscous nature of the FGM material at the sintering temperature. The sintering mismatch stress is proportional to the mismatch sintering rate. Reduced cracking under a slow cooling rate is probably due to the relaxation of residual stresses during the initial period of cooling.

A more advanced technique called Spark Plasma Sintering (SPS) or Pulsed Electric Current Sintering (PECS) (Tokita, 1999) is also used for FGM fabrication. It is a pressure-assisted sintering method in which a high current is pulsed through a die/punch/sample set-up, which can be compared with that of conventional hot pressing. The sintering mechanism and mechanical properties of the sintered compacts show characteristics different from conventional pressure-assisted sintering processes and parts. This technique offers significant advantages for various kinds of new materials and consistently produces a dense compact in a shorter sintering time and with finer grain size than conventional methods. Spark plasma sintering of FGMs can take advantage of a temperature gradient in the system, which allows a homogeneous densification of FGMs by matching the temperature gradient to the shrinkage rate gradient of the compact. With a spark plasma system, large size ceramic/metal bulk FGMs ($d = 100$ mm) can be homogeneously densified in a short time with heating up and holding times totaling less than one hour. Amongst the reported spark plasma sintered systems are WC-based materials (WC/Co, WC/Co/steel, WC/Mo), ZrO₂-based composites (ZrO₂/Steel, ZrO₂/TiAl, ZrO₂/Ni), Al₂O₃/TiAl, etc. (Tokita, 1999). A systematic introduction on the technology of spark plasma sintering can be found in a review by Tokita (1999) and a paper of Hennicke (Hennicke and Kessel, 2004), where the process, mechanical properties, size and shape effects, and production machine systems are reported.

Microwave sintering uses microwave irradiation to heat the ceramic or ceramic-based composite compact (Gerdes and Willert-Porada, 1994; Willert-Porada *et al.*, 1995; Zhao *et al.*, 2000). The mechanism of microwave heating is based on the dielectric loss of the ceramic phases involved, resulting in a volumetric heating technique in which the heat is generated by the compact itself. Microwave Sintering is another promising technique for ceramic/metal FGMs to cope with the inequality of the shrinkage rate.

Coating

Thermal spraying

Thermal spraying has been frequently used to produce FGM coatings. Thermal spraying of FGM's, offers the possibility to combine highly refractory phases with low-melting metals and allows for direct setting of the gradation profile. The powders for each component can be delivered through multiple feeders using a single torch or using separate torches.

Materials produced by thermal spraying have a porosity between 5% and 20%. It is thus particularly attractive for applications where this porosity can be tolerated or is even advantageous such as in graded NiCrAlY/YSZ thermal barrier coatings. There are a number of variants of thermal spraying. Usually, the feedstock consists of dry powder, if necessary agglomerated to improve flowability, that is fed into a plasma torch. Recently the use of liquid feedstock has been investigated where liquid means a suspension of powder but also a solution of a ceramic compound (Joshi *et al.*, 2020). This allows the build-up of coatings with a very variable microstructure including also FGM as shown in Fig. 10 (Björklund *et al.*, 2018).

Thinner graded coatings have been produced by vapor deposition processes such as conventional physical vapor deposition (PVD), electron beam physical vapor deposition (EBPVD), magnetron sputtering, chemical vapor deposition (CVD), and galvanic plating. In all of these processes the composition gradient is produced by a controlled release of the components from a source such as an anode, ingot, liquid, or gas reservoir (see Table 1 for references).

Melt Processing

Bulk FGMs containing a low-melting metal can be favorably produced by melt processing. Particles of the more refractory phase are added to the melt and the gradient is produced by sedimentation or centrifuging during solidification. The more refractory phase can also be provided as a graded preform which is infiltrated with the melt. Processes used to prepare graded preforms include sequential slip casting of dispersions with a variable content of short fibers, weaving long-fiber preforms with a variable content of spacer particles, electrochemical generation of porosity gradients in homogeneous preforms, and in-homogeneous compression of polymer foams. Table 1 gives references.

Additive Manufacturing

Additive manufacturing (AM), often also called 3D printing, is a range of processes whereby parts are built by adding material usually layer by layer directly from a computer-generated 3D model. It can be considered as a near net shape manufacturing process, which can directly manufacture complicated 3D objects without requiring molds, tooling or the need for joining or assembling.

A useful general introduction to AM across all material classes can be found in Gibson *et al.* (2021). Fig. 11 gives an overview of the different steps involved in AM starting with the computer aided design of the part. It is important to realize that computer modeling of the part is an essential activity, in fact the initial activity in AM. Generally, the workflow of AM involves several steps, starting with the modeling (geometrical modeling, materials modeling and microstructural design), slicing, simulation, manufacturing, followed by characterization, and performance analysis. Modeling is an essential part for successful AM and even more so for AM of FGM.

Fig. 10 Schematic illustration of (top) different coating architectures achievable using hybrid powder-liquid plasma spraying including also a FGM coating and (bottom) surface morphologies depicting (a) “coarse” powder derived splats, (b) “fine” splats originating from suspension/solution precursor, and (c) the mixed coarse-fine splats formed in case of a composite coating. Function-dependent coating architectures by hybrid powder-suspension plasma spraying: Injector design, processing and concept validation. *Mater. Des.* 142, 56–65.

Many AM techniques can be adapted to produce FGM components with complex geometry. Since we focus here on FGM with at least one ceramic phase and ceramics are commonly fabricated from powders we will focus here on AM methods which involve the use of powders. The present state of the art for AM manufacturing of homogeneous ceramics can be found in [Lakhdar et al. \(2021\)](#).

Ceramic AM processes can be categorized according to whether they are “single-step” or “multi-step” processes. Multi-step AM processes result in the formation of a green body that requires subsequent debinding and sintering thermal treatments in order to obtain the final part. Most AM technologies, as they have been implemented up until now, belong to this category. On the other hand, there are currently only two AM processes that have been demonstrated to be capable of directly shaping and sintering advanced ceramics in a single-step: [Fig. 12](#) provides a list of ceramic AM processes whereby the distinction between single-step and multi-step processes is made. Another type of ceramic AM is so-called negative ceramic AM. In this process a mold for suspension casting the component is made by AM, not the 3D component itself. The different processing steps in this classification are shown in [Fig. 13](#).

Many AM processes are well suited to accommodate changes in material composition since they are building up the part layer by layer. Another feature of many processes is that they can build up lattice structures. These are single material open, low density but also stiff structures. In addition, it is possible to build graded structures where the density is varied in a programmed way ([Maskery et al., 2016](#)). These are often called Functionally Graded Structures (FGS). In fact, they are a way to vary the density or porosity in a material ([Fig. 14](#)). For another example, see [Choy et al. \(2017\)](#). Some AM processes also allow varying the material composition by a mixing process as a single layer is build up. The combination of density grading and composition grading is also possible.

Direct energy deposition (DED)

DED (also known as Laser Engineered Net Shaping) is a process whereby focused thermal energy is used to fuse materials by melting. As shown in [Fig. 12](#) it is a single-step AM process so that the final geometry of the part and its final properties are defined during the AM process.

During fabrication, ceramic or metal powder particles are fed from a nozzle into the focal point of a laser beam, where the powder is fully melted and solidifies onto the substrate. [Fig. 15](#) shows how a combination of ceramic and/or metal powder and wire can also be used to manufacture composite structures. Feed rates can be adjusted during fabrication to generate composition

Fig. 11 Generic workflow for additive manufacturing from CAD to the finished part. STL is a file format that can be generated by most CAD programs and is also accepted by most AM machines. Detailed information on the different steps can be found in [Gibson *et al.* \(2021\)](#).

gradients ([Wang *et al.*, 2007](#)). Furthermore, by using several nozzles, DED also enables depositing multiple materials at a time, allowing for the direct fabrication of ceramic-ceramic ([Niu *et al.*, 2015](#)) and metal-ceramic ([Wang *et al.*, 2007](#)) composites. Besides, material composition can also be adjusted by varying the powder feed-rate, thus enabling a fine level of control over both material grading and composition grading.

However, DED has some significant limitations. In the case of ceramics, high thermal gradients and extremely fast cooling rates invariably result in the development of thermal stresses, which usually induce delamination and cracking. Therefore, the energy density of the laser beam – which is a function of laser power, beam spot size, scan spacing and scan speed – must be perfectly controlled and optimized ([Niu *et al.*, 2016](#)). This process parameter optimization is largely material dependent and must be carried out every time the composition or size and morphology of the ceramic powder/wire feedstock is modified. Other disadvantages are the limited geometrical complexity achievable, limited resolution, poor control over the shape of manufactured parts, and its low dimensional and geometrical accuracy, resulting in the need for post-machining to achieve net-shape. The DED process involves complex melting/solidification behavior, and a better understanding of the relationship between starting material composition, process parameters, microstructure, and final properties is required.

Powder bed fusion (PBF)

Similar to DED technology, PBF also uses lasers to build metal or polymer prototypes, and covers various methods including direct metal laser sintering, electron beam melting (EBM), selective laser sintering (SLS) and selective laser melting (SLM).

Direct powder bed fusion (PBF)

The term PBF encompasses AM processes where particles in a powder bed are selectively fused together under the application of a concentrated heat source ([ISO/ASTM, 2015](#)). Three well-known AM technologies fall into the general PBF category: laser melting (LM), laser sintering (LS) and electron beam melting (EBM). Whilst the first two can be used to produce ceramics, the latter is generally not applicable as most ceramic materials are not sufficiently electrically conductive. Several variants of the original laser sintering and laser melting processes, which were initially created to process polymers and metals respectively, have been investigated to adapt them to the specific requirements of ceramics. Local densification of the powder bed can be obtained either by direct laser sintering (dLS) of the ceramic powder itself or by indirect laser sintering (iLS) of a sacrificial organic or inorganic binder phase that acts as a temporary matrix for the ceramic powder until it is removed or converted to a ceramic phase by heat treatment.

Direct laser sintering (dLS)

In the PBF AM approach, called direct laser sintering (dLS), a laser selectively scans a powder bed, layer-by-layer, to fuse or sinter material. It can be applied to obtain sintered ceramic parts in a single step directly out of the AM process. The ceramic material itself is brought to a high enough temperature so that it sinters/melts. Alternatively, the laser beam can induce a chemical reaction from a non-ceramic feedstock resulting in the formation of a ceramic material in the brown or sintered state. Ideally, there is no need for post-thermal treatment nor additional densification steps after dLS. However, the inherent properties of technical ceramics, a very high melting point, low thermal shock resistance and plasticity, make dLS of ceramics significantly more challenging than with metals. Indeed, the very short laser-powder interaction time, combined with extreme temperature gradients, tend to result in poor ceramic sintering with high residual porosity and high thermal residual stress causing crack formation (Juste *et al.*, 2014; Kruth *et al.*, 2007). Nevertheless, the dLS process has been investigated for a number of technical ceramics (Lakhdar *et al.*, 2021).

Perhaps the most successful attempt to use dLS has been with reaction bonded silicon carbide (RBSiC) parts produced by dLS from a 67:33 wt/wt SiC/Si powder mixture by Meyers *et al.* (2015). The laser was used to selectively melt the Si in argon atmosphere, resulting in a porous SiSiC preform that was subsequently impregnated with a graphite suspension and infiltrated with molten Si at 1450°C. Highly dense RBSiC parts (95% TD) could be obtained after infiltration. It is debatable whether this should be considered a single-step AM process since the post-AM infiltration was an essential step of the manufacturing process to increase the density of SiSiC parts. However, the AM process still resulted in a fully ceramic part before infiltration was carried out, albeit a very porous one; in principle this process is single-step though it is multi-step in practice due to current limitations that may be overcome in the future.

Since mixtures of powders can be used in this dLS method, it should be possible in principle to induce also a gradient in composition in a direction normal to the plane of the layers, but this has not been reported.

Indirect powder bed fusion

Powder-based indirect laser sintering (p-iLS)

For completeness sake we should mention that a number of methods have been investigated which are called powder based indirect (selective) laser sintering (P-iLS; iLS; SLS; iSLS or P-SLS). In these techniques a coarse ceramic powder, typically 45–90 µm, is mixed with a low melting point polymeric or inorganic binder phase, and local sintering of the powder mix is performed through melting of the binder by the laser beam. The molten and resolidified binder provides a solid matrix for the ceramic powder and keeps the green body together. When polymeric binders are used, the part needs to be “debinded” by heating in a furnace up to a temperature where the organic is removed by decomposition, evaporation or oxidization, followed by furnace sintering at a higher temperature to obtain the final pure ceramic body. P-iLS with organic binders has been used to process a wide range of technical ceramics, including Al₂O₃, SiO₂, ZrO₂, SiC, ZrB₂, as well as apatite-mullite and apatite-wollastonite glass-ceramics. (see Lakhdar *et al.*, 2021). Inorganic binders on the other hand cannot be removed by heat treatment but need to be able

Fig. 13 Flowchart showing the number of steps of negative ceramic AM, multi-step direct AM and single-step direct AM; from AM feedstock to sintered ceramic part. to be converted to for instance a crystalline salt or a ceramic compound. Additional ceramic processing operations can be added to the workflow to enhance density, for instance by infiltration with a suspension of small particles, cold isostatic pressing prior to sintering or hot isostatic pressing (HIP).

Two pre-processing powder preparation methods were developed by Shahzad and Deckers to produce polymer-coated ceramic powders more adapted to the indirect LS process: dispersion polymerization (Deckers *et al.*, 2013) and temperature-induced phase separation (TIPS) (Deckers *et al.*, 2012a; Shahzad *et al.*, 2012, 2013, 2014). However, the benefits of these methods were limited as the formation of inter-agglomerate pores and cracks still occurred, and sintered densities between 36% and 66% only were achieved without post-processing. The same research team also investigated the influence of several post-LS densification strategies on the final density of complex-shaped alumina parts: laser remelting; cold, warm or quasi-isostatic pressing (CIP, WIP and QIP, respectively); and pressure, pressureless or vacuum infiltration of the green or brown body with alumina suspensions (Deckers *et al.*, 2012a,b).

Other powder bed based techniques

Binder jetting

Powder bed-based binder jetting is the oldest AM technique invented at MIT in the 1980s (Sachs *et al.*, 1993). 3D structures are generated by placing droplets of binder in computer selected spots in a powder bed of coarse ceramic powder. Locally powder particles are bound together whereas elsewhere they stay loose. When the binder printing is terminated the loose powder is removed and the remaining shaped green body can be further processed by debinding and sintering steps.

One intrinsic limitation of PB processes, including also powder bed fusion and powder bed sintering, comes from the use of dry powders to deposit layers of ceramic material. Only coarse ceramic particles can be used to form layers in dry PBF processes, because fine submicron ceramic powders are subjected to agglomeration by Van der Waals inter-particle forces during layering, which leads to poor powder flow and preventing the formation of uniform powder layers. The use of coarse powders leads to a low density of the final sintered parts. Additional processing steps in the workflow such as isostatic pressing can remedy the situation somewhat but can generally only partially solve the problem of the poor packing density of

the ceramic feedstock that is used for layer formation. Increasing the packing density of the powder bed remains the most critical issue to address in order to prevent the formation of inter-particle and inter agglomerate pores and enable the direct production of fully-dense parts.

One approach that researchers have started to investigate is the incorporation of small amounts of nanoparticles into the binder liquid in order to fill the interparticle voids in the powder bed with finer powders, whereas another approach lies in the use of colloidal slurries instead of coarse dry powders.

Slurry based binder jetting

In Slurry-based binder jetting (s-BJ) the powder bed is formed by depositing layers of ceramic slurries instead of dry powders. Submicron powders can be used which improve the powder bed packing density and therefore also increase green and sintered densities. (Sachs *et al.*, 1993; Grau, 1998; Moon *et al.*, 2000; Kernan *et al.*, 2007). Ceramic green layers can be deposited by different techniques (inkjet printing, slip casting, doctor blading) (Grau, 1998).

As already mentioned, since mixtures of powders can be used, either with dry powders or with slurries it should be possible in principle to induce also a gradient in composition normal to the plane of the layers, but this has not been reported.

Sheet lamination

Sheet lamination processes such as laminated object manufacturing (LOM) and its variants, fabricate desired objects by joining different layers and foils. For each layer, the outline of the part is first cut with a computer-controlled knife or CO₂ laser. Layers are sequentially stacked, cut and bonded. Ceramic green tapes may be produced by tape casting (Cui *et al.*, 2003), extrusion (Weisensel *et al.*, 2004; Zhang *et al.*, 1999), or preceramic paper (polymer) (Windsheimer *et al.*, 2007), to form the desired geometry. A heated roller is then applied on the surface to thermally activate the binder and promote bonding between adjacent layers. LOM works at low temperature and rolling pressure, which helps minimize issues with warping and delamination. The resulting green body needs to be debinded and sintered.

Only few examples in the literature related to FGMs using sheet lamination are found (Zhang *et al.*, 2001; Zeng *et al.*, 2000).

Materials extrusion

Ceramic material extrusion

In this AM process, a ceramic-loaded paste, or polymer filament, or a preceramic polymer filament, is extruded through a nozzle and deposited onto a platform layer-by-layer to form a 3D green body. There are many variants of this process and accordingly also a many different names and acronyms. An overview of these can be found in Lakhdar *et al.* (2021). Important advantages of these ceramic extrusion processes are their relative ease of operation as well as the low manufacturing costs since a high-energy beam is not involved.

The success of these material extrusion processes relies on the precise control of the rheological properties of the extruded paste or filament. Feedstocks must have a high solid loading of well-dispersed ceramic particles to minimize shrinkage and prevent the formation of porosity and cracks during debinding and sintering heat treatments. They must also have a pseudoplastic (shear-thinning) behavior to ensure that the very high starting viscosity decreases by several orders of magnitude when subjected to a small increase in shear rate inside the nozzle during deposition (Baer *et al.*, 1997). These viscoelastic materials are formulated to have a significant yield stress (Fu *et al.*, 2011). Yield stress increases with ceramic loading as well as with the addition of a viscosifying binder. Pastes suitable for extrusion typically have yield stress values ranging between 100 and 1000 Pa (Leu *et al.*, 2011; Rueschhoff *et al.*, 2016; Schlördt *et al.*, 2013; Costakis *et al.*, 2016). There are two main types of ceramic material extrusion processes: (1) wax-based extrusion processes, and (2) water-based extrusion processes.

In wax-based ceramic material extrusion processes, ceramic powders are suspended in a polymeric dispersion medium, and the resulting polymer/ceramic composite paste or filament is extruded through a small orifice onto a platform. Upon deposition the molten feedstock needs to solidify to give strength to the green body as it is built. For polymer-based filament the paste will solidify as the temperature drops below the polymer glass-transition temperature.

These extrusion techniques are well suited to create FGM materials. Scheithauer *et al.* (2015) developed a process called Thermoplastic 3D printing (T3DP), that combines the additive fabrication of metal, ceramic and metal-ceramic composites, and used it to fabricate FGM structure with alternating dense (> 99% TD) and porous (~5% porosity) regions by co-depositing a 36 vol% zirconia suspension and a zirconia suspension containing 5 vol% polysaccharide powder as a pore-forming agent, respectively (Scheithauer *et al.*, 2017).

R&D on wax-based extrusion processes has been reduced in recent years in favor of water-based ceramic extrusion processes. These aqueous pastes are typically characterized by a high ceramic powder loading and a low organic content. Several variants of the ceramic extrusion process are based on this approach. These water-based extrusion techniques have a number of advantages compared to wax-based extrusion: (1) high green densities, (2) simplified debinding schedule, (3) low sintering shrinkage, (4) environmentally-friendly, (5) low cost of feedstock and hardware (Baer *et al.*, 1997).

A well-known example of such a technique is the robocasting process developed by Cesarano *et al.* (1998) at Sandia National Laboratories, USA. In robocasting, which is also often called direct ink writing (DIW), a highly loaded viscous ceramic paste is extruded through a nozzle at ambient temperature and solidifies onto the substrate upon drying in air (Baer *et al.*, 1997). Suspension solidification and shape retention after deposition is due to evaporation of the solvent and the pseudoplastic to dilatant transition that it induces. Other aqueous paste formulations have been developed such as reversible colloidal gels that can coagulate by

Fig. 16 Gradient 3D printing system. (a) Schematics of the gradient 3D printing mechanical setup and printing control system. (b) Process of gradient 3D printing. Reproduced from Ren, L., Song, Z., Liu, H., *et al.*, 2018. 3D printing of materials with spatially non-linearly varying properties. *Mater. Des.* 156, 470. Published by Elsevier.

controlled flocculation with additions of salts or polyelectrolytes, which set immediately after deposition without drying (Tuttle Bruce *et al.*, 2001; Smay *et al.*, 2002; Nadkarni and Smay, 2006; Feilden *et al.*, 2016). These colloidal inks display improved shape retention properties for the fabrication of free spanning geometries such as lattices (Fig. 14) without support structures.

In freeze-form extrusion fabrication (FEF) an aqueous ceramic suspension or colloidal gel is extruded through a nozzle and frozen onto the cold substrate as it is deposited. A triple-extruder FEF system was developed to fabricate parts with functionally graded material (FGM) structure. Test bars with discrete material grading were produced by varying $\text{Al}_2\text{O}_3/\text{ZrO}_2$ ratios from 100% Al_2O_3 to 50% Al_2O_3 –50% ZrO_2 (Leu *et al.*, 2011, 2012). FGM parts from aqueous-based colloidal suspensions of ZrC and W consisting of a graded composition from 100% ZrC to 50%W–50%ZrC were also produced (Li *et al.*, 2012).

Another variant of water based ceramic extrusion is called ceramic on-demand extrusion (CODE). An aqueous ceramic paste (50–60 vol%) is extruded using an Auger valve onto a substrate located in a tank designed to hold a fluid. After each layer is deposited, a mineral oil is pumped into the tank at a controlled-flow rate to a level just below the top surface of the layer. Infrared heating is then applied to partially dry the layer, with the oil precluding undesirable non-uniform water evaporation from the sides, thus preventing warpage and crack formation. With CODE, FGM specimens could be produced with a compositional gradient extending from pure Al_2O_3 to $\text{Al}_2\text{O}_3/\text{ZrO}_2$ with varying composition (Li *et al.*, 2018b). A 1% average error in material composition was observed compared to the original design of compositions, and it was found that greater material composition gradients led to larger delamination and curling.

The material extrusion method usually uses a single- or multiple extruders, each extruding a paste of materials layer-by-layer. A multi-nozzle device allows for the production of arbitrary components by controlling the flow ratio of different pastes. Fabrication of FGMs with linearly varying properties has been realized with a wide range of material extrusion techniques. Continued development of equipment and technologies has made it possible to produce a material with nonlinear gradients. Ren *et al.* (2018) developed a 3D printer equipped with a three- axis motion gantry, an active mixing device and a digital material feeding

device (**Fig. 16(a)**). During the printing process, mathematical functions were used to depict the graded distribution of material properties. Then, through gray-scale representation and controlling code generation, nano-sized Al_2O_3 particles were digitally fed into the printer to fabricate 1D, 2D, and 3D graded objects as shown in **Fig. 16(b)**.

Direct inkjet printing (DIP)

Material jetting is defined as an AM process in which droplets of build material are selectively deposited to directly shape 3D parts onto a substrate (*ISO/ASTM, 2015*). Material jetting is usually called direct inkjet printing (DIP). In DIP, the jetted ink is either (1) a well-dispersed suspension of submicron ceramic particles in water or an organic solvent, or (2) a wax-based ink containing submicron ceramic particles.

A continuous flow (CIJ) and a drop on demand (DoD) approach is possible (*Vaezi et al., 2013a*). In continuous inkjet printing (CIJ), an uninterrupted flow of individual droplets of electrically charged ink is generated. Unwanted droplets are caught before hitting the substrate using deflecting electrodes. These unprinted droplets are captured and can be reused.

DoD on the other hand is a non-continuous approach where individual droplets are generated by the pressure pulses induced by for instance the excitation of a piezoelectric actuator at controlled frequencies. Hence ink droplets are deposited only when and where required. Whilst the building rate of DoD is slower than that of CIJ, its wider range of jettable materials, lower risk for ink contamination, higher resolution, and better accuracy make it more suited to the fabrication of 3D objects (*Vaezi et al., 2013b*). DoD inkjet printing performance is highly dependent on the physical properties of the ink, particularly its viscosity and surface tension (*Jo et al., 2009*). Beside ink properties, printing parameters such as jetting frequency, travel speed, acoustic wave speed, and nozzle-substrate distance also have a strong influence on the jetability (*Reis and Derby, 2000; Reis et al., 1999*). Because jetting nozzles typically have a diameter between 10 and 60 μm , only fine submicrometric or nanopowders must be used in order to avoid nozzle clogging and improve suspension stability. It is vital that the ceramic solid loading be high enough so that a high green density can be obtained as well as to avoid issues with excessive shrinkage and cracking, whilst ensuring viscosity remains low enough for the ink to be printable. Therefore, powder loading is usually formulated in the range 20–30 vol% (*Seerden et al., 1999*).

Advantages and limitations of DIP

DIP is characterized by a high resolution thanks to the deposition of droplets with a volume of a few picolitres. Fully dense components with an excellent surface finish can be obtained. Solvent-DIP enables the fabrication of green parts containing very low amounts of organics, providing improved sintering behavior and a lower linear shrinkage upon firing. Aqueous-DIP in particular is desirable for a more environmentally friendly and less hazardous alternative to organic solvent-based DIP.

The suitability of DIP for manufacturing dense fully ceramic parts from both oxide and non-oxide ceramic materials has already been demonstrated. DIP can be used to shape any ceramic material as long as a stable suspension of submicron powders with the required physical properties for jetting can be formulated. The use of submicron or nanoparticles results in a higher particle packing in the green body and a higher sintering activity, which are both highly beneficial to the final density of printed products. By the use of multiple printheads DIP has the unique advantage over all other AM technologies in the ability to deposit droplets of multiple materials simultaneously. This enables the fabrication of FGMs and in fact microstructure tailoring on a voxel-level. *Mott and Evans (1999)* fabricated a one-dimensional $\text{ZrO}_2/\text{Al}_2\text{O}_3$ FGM but experienced issues with differential sintering and cracking. *Gingter et al. (2015)* manufactured 3Y-TZP/ Al_2O_3 FGMs cylinders with a diameter of 10 mm; cylinders made of 800 individual layers with a 2 μm thickness were printed on a substrate at 80°C. A high sintered density was obtained (97.5% TD). Simultaneous jetting is also useful for the deposition of droplets of support material, and it has already been used to print sacrificial support structures based on carbon black to enable the fabrication of complex shapes and overhangs such as dental bridge frameworks (*Özkol et al., 2012*).

Vat photopolymerization

Vat photopolymerization is a lithography-based AM process in which a liquid photopolymer in a vat is selectively cured by light-activated polymerization" (*ISO/ASTM, 2015*). To manufacture ceramic parts using lithography-based processes, fine ceramic powders are dispersed into the liquid photopolymer to form a UV-curable slurry (*Chartier et al., 2002; Snelling, 2013; Hinczewski et al., 1998*). Alternatively, the process can be based on the photopolymerization of UV-curable liquid preceramic polymers (*Zhou et al., 2010*).

The reactive colloidal system consists of monomer, photo initiator, submicron ceramic particles, dispersant, and additional additives such as diluent and solvent. Upon curing by UV light, the photopolymer acts as a matrix for the ceramic particles and provides shape, cohesion, and strength to the green part. The green body is subjected to a binder burnout heat treatment to ensure complete removal of the polymer matrix and then sintering to yield the final ceramic part. Several technological variants of the vat photopolymerization process exist for the layerwise freeform fabrication of ceramic components: stereolithography (SL), Digital Light Processing (DLP).

In SL, selective solidification of the liquid photocurable resin suspension is induced by a UV laser that is steered using a scanning galvanometer mirror positioning system to scan selectively the resin surface at the locations specified by the STL file.

DLP, which has also been called Direct Photo Shaping Large Area Maskless Photopolymerization (LAMP) or Mask-Image-Projection-based Stereolithography (MIP-SL) has at its core the digital micromirror device (DMD) technology. A DMD chip is a digitally controlled micro-opto-electro-mechanical system (MOEMS) invented at Texas Instruments in 1987 made of a 2D array composed of several hundred thousand individually switchable micromirrors producing a dynamic image that is projected onto

the photopolymer surface. The main advantage of DLP over laser-based SL is its much greater manufacturing speed, because the entire surface of the polymer is cured at once, whilst SL provides a point-based photopolymerization method. Different types of homogeneous ceramics have been fabricated using both techniques with good properties (Lakhdar *et al.*, 2021), although there are limitations in the choice of ceramic. Depending on the details of the implementation of the technique it should be possible to fabricate FGM ceramics with a gradient normal to the layer direction, i.e., normal to the surface of the bath, but this potential has not yet been explored.

Applications

The abrupt change in mechanical behavior (stiffness) at the interfaces between dissimilar materials in monolithic form can easily lead to weak interfaces and mechanical failure. Compared with monolithic composites, FGMs can be much more robust because their gradient interfaces can help minimize thermo-mechanical stress concentrations, hence preventing delaminations and improving the lifetime of load bearing structures.

The advantages of gradient materials are not restricted though to structural applications. Gradients can display functional properties that cannot be achieved by a homogeneous material or directly joined material. Indeed, one of the earliest uses of property gradients in functional materials were graded refractive index lenses and graded refractive index glass fibers for data transmission which allow outstanding transfer rates even for long transmission paths (Uchida *et al.*, 1970). Additionally, the absence of sharp interfaces in FGMs offers the chance to eliminate undesired effects of interfaces such as reflections of electromagnetic or acoustic waves or pile-up of dislocations in hetero-epitaxy. Such tailor-made properties make FGM's attractive for many acoustic, optic, electronic, magnetic, piezoelectric, thermoelectric, and photovoltaic applications.

The practical use of FGMs in industry is still very limited. There are, however, a few examples of early applications of materials that are FGMs by definition. Already in the 1960s glass/metal joints with a gradient in thermal expansion coefficient were used to reduce thermal stresses at the interface of the two materials and thus prevent failure of the glass/metal joint. Glasses with graded refractive index were developed in the early 1970s and were probably the first materials in which a very specific and precise gradation profile was essential for application. A circular plate with a gradient in refractive index can act as a miniature focusing lens with no spherical aberration. Glass rods with a radial index gradient drawn to a fiber can be used in wide-band optical fiber cables. Another well-established application of FGMs is in polymer skin foams with a dense surface layer and an increasing porosity towards the interior. These foams can provide high impact strength at low weight in applications such as instrument panels.

All the materials mentioned above are graded glasses or polymers, which are comparatively easy to manufacture. Gradient composite materials consisting of components with strongly different properties, i.e., graded ceramic/metal or ceramic/ceramic composites, have been manufactured only since the 1990s and tests of graded components from such materials in a real environment are still a rarity. Therefore, they are not widely used in commercial products. Nevertheless, they are expected to provide useful solutions for challenging engineering problems (Miyamoto *et al.*, 1999). The rapid development of additive manufacturing techniques has increased the prospects of applying the FGM concept in practice. In particular for polymer based and metallic materials systems industrial applications may be on the horizon. For ceramics and in particular when the ceramic phase has to be the majority phase, the technical difficulties are higher as should have become clear from the discussion above.

Nevertheless, FGMs for ceramics are worthy of continued research. They promise and they will enable solutions where the material operating conditions are severe. For example, wear-resistant linings for handling large heavy abrasive ore particles, very high-speed cutting tools, rocket and space plane heat shields, heat exchanger tubes, thermoelectric generators, heat-engine components, plasma facings for fusion reactors, and electrically insulating metal/ceramic joints, generally, ceramic-metal FGMs for minimizing the thermo-mechanical mismatch in metal-ceramic bonding. As shown in Fig. 3 a stress discontinuity is generated in case of a bi-material combination, which may result in poor adhesion or even delamination, whereas a significantly lower stress concentration can be established for a graded interface, thereby improving the materials adhesion and reducing the probability of delamination.

Mechanical Properties and Applications

In recent years, polymer/ceramic/metal-based FGMs made by AM have been widely studied to overcome the shortcomings (such as crack initiation and propagation) of each of the individual components. By monitoring and simulating the forces acting on a topology optimized quadcopter's arm, Li *et al.* (2018a) designed a lightweight, functionally graded, cellular structured quadcopter's arm without compromising its performance compared to a traditionally designed structure. Both simulation and experimental data showed that the optimized FGSs could significantly improve the structural stiffness of a quadcopter's arm. FGSs may improve and optimize mechanical behavior of a component by reducing mass without sacrificing load-bearing capabilities.

Graded gyroid cellular structures (GCS), a kind of functionally graded cellular structure with the gradient parallel to the loading direction, exhibited layer by-layer deformation and failure behavior. Mathematical models were developed to predict and customize the mechanical properties of GCS by optimizing the relative density of each layer (Yang *et al.*, 2019).

Cambridge: Woodhead Publishing Limited. pp. 575–596.

Wear protection

The wear resistance of tools can be substantially increased by a hard surface layer in a compressive stress state (Lin *et al.*, 1998). However, if a coating is under compressive stress the risk of delamination is considerable for many material combinations. A WC/Co FGM with a gradual variation in cobalt binder content from the surface to the interior will develop a compressive stress state at the surface. However as explained by Fig. 3 spallation of the top layer is unlikely to occur. Sandvik AB and Sumitomo Electric Industries already use this concept in tools for special applications such as drill bits. The improved resistance to delamination of an FGM coating was also exploited in an FGM cutting tool where a diamond surface layer was applied to a SiC substrate. Such a tool has a very high cutting precision due to its high stiffness compared to a tool based on a metallic alloy substrate (Li *et al.*, 1994).

A 3D gel-printed TiC-high manganese steel cermet showed gradient distributions in density, hardness, transverse failure strength, abrasion wear resistance and impact toughness due to its graded structure (Zhang *et al.*, 2018).

Using graded WC/Co hardmetals, it is possible to improve wear resistance and toughness at the same time (Fig. 17). This can be achieved by a gradation in the binder content from the center to the surface of the tool. The improved mechanical properties of the FGM cemented carbide are due to compressive stresses near the surface, which enable a reduction of the Co-phase content from 6 to 3 wt% without any loss in apparent fracture toughness.

Two existing industrial technologies have been reported to produce graded WC-Co hardmetals, i.e., liquid phase sintering of homogeneous WC-Co in a controlled atmosphere or pressure assisted sintering of graded WC-Co compacts. The first method is mainly used for nitride-containing WC-Co or WC-Ni cermets (Chen *et al.*, 2000a; Narasimhan *et al.*, 1995). The graded Co distribution is formed during liquid phase sintering through the establishment of a nitrogen partial pressure gradient (Zackrisson *et al.*, 2000; Chen *et al.*, 2000b) or by a high temperature carburization treatment of a WC-Co composite with sub-stoichiometric

Fig. 19 Weibull plot of the biaxial strength (ISO 6474) of homogeneous Al_2O_3 and $\text{Al}_2\text{O}_3/\text{ZrO}_2$ FGM disks with 80 vol% Al_2O_3 in the core, pure Al_2O_3 on the outside and intermediated convex graded profile. The FGM disks were made by electrophoretic deposition and pressureless sintering. Reproduced from Anné, G., Vleugels, J., Van der Biest, O., 2006. Functionally graded ceramics. In: Low, I.M. (Ed.), *Ceramic-Matrix Composites: Microstructure, Properties and Applications*. Cambridge: Woodhead Publishing Limited. pp. 575–596.

Fig. 20 Wear volume of step-graded $\text{Al}_2\text{O}_3/\text{ZrO}_2$ FGM disks with 80 vol% Al_2O_3 in the core and pure Al_2O_3 on the outside (data from Novak *et al.*, 2007). Reproduced from Anné, G., Vleugels, J., Van der Biest, O., 2006. Functionally graded ceramics. In: Low, I.M. (Ed.), *Ceramic-Matrix Composites: Microstructure, Properties and Applications*. Cambridge: Woodhead Publishing Limited. pp. 575–596; Woodhead publishing is now owned by Elsevier.

carbon content (Fischer *et al.*, 1988). Pressure assisted sintering techniques such as hot pressing, hot isostatic pressing and SPS can also be used to consolidate graded WC-Co compacts by solid state sintering (Tokita, 2003). Microwave sintering methods of graded WC/Co cemented carbides have also been reported (Willert-Porada *et al.*, 1995).

Other graded cermet systems reported include $\text{Cr}_3\text{C}_2/\text{Ni}$ (Seefeld *et al.*, 1999), TiC/Ti (Cline, 1995), and TiC/Ni (Sabatello *et al.*, 2000). The design concept of the graded cermets is similar to that of WC/Co cemented carbide FGMs.

As mentioned above residual stresses have a large influence on the properties of a structural body. They can be detrimental, but they can also be taken advantage of. For instance, a correct design of the composition gradient can generate compressive stresses at those locations, which are loaded in tension during application. The stresses can be calculated using finite element methods for the more complex geometries. For simple geometries such as in Fig. 2, analytical methods can be used.

Fig. 18 shows the results for an $\text{Al}_2\text{O}_3/\text{ZrO}_2$ FGM disk with homogeneous pure Al_2O_3 surface layers, a homogeneous $\text{Al}_2\text{O}_3/\text{ZrO}_2$ composite core and intermediate graded layers with a convex, linear and concave profile. The composition profiles and corresponding residual stresses for the FGM disks sintered at 1550°C are shown. These calculations reveal that the FGM disks with a convex ($n = 0.5$) alumina gradient profile result in the highest compressive stress in the alumina outer layers and the lowest tensile stresses in their core. Compressive surface stresses in the outer alumina layer have a beneficial effect on the strength (Fig. 19) and the wear resistance (Fig. 20). Additionally, an increased toughness can be observed in this kind of graded ceramic composite (Tilbrook, 2005).

Thermal Protection Systems

One of the earliest applications of the FGM concept was the thermal protection of space re-entry vehicles. A SiC/C FGM nose cone for a space plane was developed at the Japanese National Aerospace Laboratory. A nose cone with a SiC protection layer on a C/C

Fig. 21 (Left) Overview of $\text{Al}_2\text{O}_3/\text{TZP}$ FGM ball-heads for hip prostheses, made by electrophoretic deposition; (Right) residual stress analysis of FGM ball heads; the outer surface is pure alumina; the core is about 20 vol% zirconia. The color is a measure of the residual stress. Red corresponds to the highest tensile stress; blue corresponds to the highest compressive stresses. Reproduced from Anné, G., Vleugels, J., Van der Biest, O., 2006. Functionally graded ceramics. In: Low, I.M. (Ed.), *Ceramic-Matrix Composites: Microstructure, Properties and Applications*. Cambridge: Woodhead Publishing Limited. pp. 575–596; Woodhead publishing is now owned by Elsevier.

composite exposed to a supersonic gas flow at 1900°C deteriorated after the first thermal cycle. In contrast, a nose cone with an additional graded SiC/C interlayer did not show any change after 10 cycles (Sohda *et al.*, 1993).

Turbine blades of gas turbines must withstand high stresses at elevated temperatures and are thus made from superalloys. The efficiency of the turbine increases with increasing gas inlet temperature and thus the superalloy is coated with a bond coat of NiCrAlY and a heat-insulating layer of ZrO_2 in state-of-the-art gas turbines. The major mechanism limiting the lifetime of such a thermal barrier coating (TBC) is the growth of an oxide layer of alumina at the interface of the bond coat and the ZrO_2 which causes stresses and, ultimately, spallation of the TBC. A gradation of the zirconia coating and the bond coat improved considerably the resistance of the coating to spallation in thermal cycling experiments (Kawasaki and Watanabe, 1999). However, it is expected that the oxidation resistance and thus the long-term stability of such a graded system will be insufficient due to the dispersed metal particles in the graded layer. It has therefore been proposed to introduce an additional graded alumina layer between the bond coat and the zirconia. It is not clear yet whether such a design will provide a substantial long-term improvement compared to conventional TBCs.

FGMs were investigated to improve the durability of heat exchangers. With the development of hypersonic vehicles, more complex geometries have been applied to the design of integrated thermal protection (ITP) structures. Inspired by the structure of the spruce stem, Kaijie *et al.* (2019) used SLM to fabricate a series of ITP structures consisting of hollow tubular sections with graded diameters. They achieved a bottom surface temperature 21°C lower than that of non-graded structures. Additive manufacturing of a functionally graded material from Ti-6Al-4V to Invar was reported by Bobbio *et al.* (2017). The properties of a wire arc additively manufactured titanium aluminide FGM for high temperature service were described by Wang *et al.* (2018).

Medical Implants

ZrO_2 -based FGMs have been of high interest (Marple and Boulanger, 1994; Anné *et al.*, 2004; Zhao *et al.*, 2000; Put *et al.*, 2002) because of the high toughness and excellent strength of tetragonal ZrO_2 polycrystalline ceramics (TZP). ZrO_2 -based FGMs are mainly developed for energy conversion systems (turbine blades) and for cutting tools, where a high hardness has to be combined with high toughness or where thermal stresses have to be released (Sanchez-Herencia *et al.*, 2000).

Both Al_2O_3 and ZrO_2 are biocompatible materials. Pure high strength Al_2O_3 is in fact used for total hip prostheses comprising both the femur head and the hip bearing. The motion of ceramic against another ceramic surface generates a very low amount of wear. Today, a majority of the joint prostheses consist of metallic components, articulating against polymer counterparts, of which more than 10% need revision after only 10 years. This is expensive and reduces the quality of life of the patients. Also, the clinical effects of metallic ion releasing implants and polymer wear debris are a matter of concern. This demonstrates the need for more wear resistant and biocompatible materials such as ceramics. $\text{Al}_2\text{O}_3/\text{ZrO}_2$ FGMs were studied intensively for biomedical applications, specifically for implants like hip prostheses (Anné *et al.*, 2004). The FGM idea was applied to increase the performance of total hip replacement prostheses through design and development of alumina/zirconia functionally graded materials using electrophoretic deposition as a near-net shaping technique (Fig. 21). Therefore alumina-zirconia graded femoral ball-heads were developed. The potential of this system follows from the properties of alumina (low wear, high hardness) and zirconia (high strength, high toughness). By combining alumina and zirconia, a functional gradient in hardness (high at the alumina surface) and toughness (high in the zirconia rich core) can be established. Due to the difference in thermal expansion coefficient of Al_2O_3 and ZrO_2 , residual stresses are developed during cooling from the sintering temperature, with a compressive stress at the surface and tensile stress in the core of the material (Fig. 21). These strongly influence the mechanical properties like strength and toughness.

It is generally acknowledged that a porous surface of a bioactive material such as hydroxyapatite is ideal for rapid bone ingrowth and good mechanical bonding in prosthetic devices. However, for the sake of mechanical stability it is often necessary to use metals as load-carrying materials in implants. As a result, titanium coated with hydroxyapatite is used as an implant material. The adhesion of hydroxyapatite on titanium is only moderate and failure of the interface may occur after implantation. However, it has been demonstrated that the bonding of certain glasses to titanium is quite strong. Therefore, a coating of glass on a Ti-6Al-4V substrate possessing an increasing volume fraction of hydroxyapatite and pores close to its outer surface is an excellent material for cementless artificial joints and dental implants. Such a graded composite showed a good apposition *in vivo*, and the pull-out strength of dog femur implants was three times higher than that of a sandblasted titanium implant (Maruno *et al.*, 1999). The pull-out strength increased with time due to bone growth into the interior of the coating layer, and after 76 months of plantation no separation of the glass layer from the titanium was observed. A graded composite of this type therefore has a considerable potential as cementless artificial joint or endosseous dental implant.

Future Outlook

Already a lot of scientific work has been established in processing graded bulk ceramics and in modeling and optimization of the properties of these materials. Despite these technological successes, the number of commercial successes is still limited because the production costs are in most cases still too high compared to homogeneous materials. However, new production processes such as additive manufacturing (AM) are emerging on the market. They are expected to allow the production of FGM bulk ceramics and ceramic-metal FGM in an economical way.

Many new target applications have appeared or new ones are emerging, including (see also Li *et al.* (2020)):

- (1) Thermo mechanical applications.
- (2) Energy conversion.
- (3) Applications in optics and electronics.
- (4) Electric and magnetic applications.
- (5) Graded cemented carbide coatings on steel substrates.
- (6) Biomedical applications.

Additional Information

Since 1990, an international congress on Functional Graded Materials is organized by the International Advisory Committee of FGM (IACFGM) every 2 years. The proceedings of these congresses, although sometimes not easily available, give a lot of information about research on FGM materials. The symposia on FGM's were held in Sendai (1990), San Francisco (1992), Lausanne (1994), Tsukuba (1996), Dresden (1998), Estes Park (U.S., 2000), Beijing (2002), Leuven (2004), Hawaii (2006), Sendai (2008), Guimaraes (2010), Sao Paulo, Brazil (2014), Bayreuth (2016), Kitakyushu, Japan (2018). The 16th International Symposium on Functionally Graded Materials will take place in Hartford Connecticut, US, August 7–10, 2022.

Introduction

Transparent ceramics exhibit a great-variety of desirable and/or unique properties and property combinations that are often unachievable with other materials, enabling applications ranging from transparent armor and electronics to laser hosts. Metals and alloys are opaque, leaving polymers, glasses, glass-ceramics and ceramics as transparent materials. Polymers, glasses and glass-ceramics can have excellent visible transparency, low density, high toughness (polymers) and low cost, but they generally have poor infrared transparency and thermal resistance and are relatively soft (Tropf *et al.*, 2000). Whereas, ceramics transmit further into the ultraviolet and infrared than any other materials while exhibiting a wide-range of refractive indices (Harris, 1999). They can also exhibit much higher hardness, strength and stiffness; the potential for far higher toughness than glasses; and higher thermal, thermal-shock, thermal conductivity and chemical resistance, as well as much broader ranges for some of these properties. Moreover, transparent ceramics can exhibit properties such as luminescence, lasing, electronic properties varying from insulating to electronic or ionic conduction, ferroelectricity, and electro- and magneto-optic behavior. Furthermore, interesting combinations exist, such as visible and infrared transparency combined with high strength and hardness and thermal shock resistance (Goldstein and Krell, 2016). As such, for some applications, only transparent ceramics can suffice.

This chapter focusses on crystalline materials that are transparent in the visible and/or infrared and have ‘ceramic’ (non-metallic/polymeric) properties. Although they are important infrared materials, low-bandgap semiconductors like silicon, germanium and gallium arsenide are not described. ‘Ceramic’ also refers to polycrystalline material, which is the focus of this chapter. However, single crystals representing important applications are also discussed. Although transparent single crystals were produced as early as the 1800s, transparent polycrystalline varieties were not realized until the 1950s and 60’s, and even then, only as small samples with poor transmission. While they are a relatively recent addition, transparent ceramics are rapidly expanding and are now used in a broad-range of applications (Goldstein and Krell, 2016; Evans, 2020). Moreover, despite often being used in only small quantities, they frequently enable the applications they are used in. This chapter provides an introduction to transparent ceramics and describes common materials and their processing, properties and applications.

Transmission Physics

Due to non-zero bandgaps, ceramics are transparent to at least some wavelengths of the electromagnetic spectrum. Of interest are the ultraviolet (UV, 10–380 nm), visible (Vis, 380–780 nm), infrared (IR, 0.78–1000 μm) and sometimes the microwave (MW, 1–100 mm). Within these ranges, absorption by atmospheric gases gives rise to windows in the visible, and in the near (NIR, 0.78–1 μm), shortwave (SWIR, 1.4–3 μm), midwave (MWIR, 3–5 μm) and longwave (LWIR, 8–14 μm) infrared (Harris, 1999; Goldstein and Krell, 2016).

Light interacts with ceramics primarily by interaction of its electric field with valence electrons. Shorter wavelengths, with higher energy than the bandgap ($E = hc/\lambda$, where h is Planck’s constant, c the speed of light in vacuum and λ wavelength), are absorbed by exciting electrons to the conduction band. In turn, excited electrons can lose energy by interacting with phonon (vibrational) modes and generating thermal energy and/or by relaxing to their ground state and re-emitting (luminescence), typically at lower frequency. Whereas, longer wavelengths are absorbed and transformed to thermal energy by phonon interactions. Both the short- and long-wave absorption edges are gradual, characterized by the Urbach and multi-phonon absorption tails, respectively (Savage, 1991). Wavelengths between the intrinsic absorption edges constitute the transmission window, where the alternating electric field polarizes atoms and accelerates electrons, which subsequently omnidirectionally re-radiate at the same frequency (Huygens’ principle). Interference between re-radiated intensities results in propagation through the material. Moreover, when a wavefront, or a planar array of intensities containing image information is incident upon the smooth planar interface of a transparent window, interference between re-radiated intensities results in only reflected (specular) and refracted (transmitted) intensities, the latter transmitting the image information through the window (Tropf *et al.*, 2000; Saleh and Teich, 1991) (Fig. 1).

Reflected and transmitted intensities (reflectance, transmittance) at interfaces depend on the media on either side, incidence angle, wavelength and electric field orientation (polarization). The speed of light is reduced due to interaction with matter, as quantified by the refractive index; $n = c/v$, where v is the phase velocity in the medium. In turn, the refractive index depends on a medium’s atoms and their structure, crystallographic orientation and state. The greater the interaction, the higher the index and the intrinsic reflection (reflectivity), which in turn limits maximum theoretical transmittance. In vacuum and approximately in air, the reflectivity of the surface of a medium with refractive index n is given by $R_1 = (n - 1/n + 1)^2$ and $R_2 = 2R_1/(1 + R_1)$ for a window with two interfaces (Fresnel’s equations). A full description of attenuation (α) due to high intrinsic absorption near absorption edges is given by the complex refractive index; $N = n - ik$, where $k = \alpha\lambda/4\pi$. However, since k is usually small within the transmission window, n is a good approximation (Harris, 1999; Saleh and Teich, 1991).

Fig. 1 Light transmission through a polycrystalline ceramic window. Transmitted intensity is decreased by specular and diffuse reflection at both interfaces, internal scatter (including birefringence) and absorption. Non-specular backscatter includes diffuse reflection and contributions from internal scatter, while forward scatter is comprised of internal scatter contributions, birefringence and diffuse refraction.

Reflection can significantly decrease the transmittance of windows and optical components for high-index materials, but it can be reduced with antireflective coatings. Since reflectance increases as the difference between the refractive indices bounding interfaces increases, coating with lower-index materials lowers reflectance at air/coating interfaces. The coating refractive index for maximum transmittance is the geometric mean of the refractive indices bounding interfaces; $n_{\text{coating}} = \sqrt{n_{\text{air}} \cdot n_{\text{substrate}}}$, which also corresponds to equal reflection intensities from each interface (Harris, 1999). Although coatings add an additional reflection at coating/substrate interfaces, the net reflection is still lower than without a coating. For example, a window with $n = 2$ suffers an 11% reflection at the air/window interface. By adding a coating with $n = 1.4$, the air/coating and coating/window losses are 3% each (6% total). Moreover, if the coating thickness is $\frac{1}{4}$ of a wavelength of interest, the air/surface and coating/bulk reflections destructively interfere since they are 180° out-of-phase, reducing reflection to zero near that wavelength (even for higher-index coatings). Conversely, high-index coatings can be used to increase reflection or to reject unwanted wavelengths (such as for heat-mirrors), for UV protection and to protect sensitive electronics and detectors. Reflection can also be modified by using multi-layer coatings, grading the refractive index or using moth-eye coatings. Interference of multiply-reflected and transmitted intensities can also affect transmission in thin components (Etalon effect) (Harris, 1999).

The refractive index varies with wavelength (dispersion) and is described by empirical Sellmeier relations within the transmission window. The magnitude of the variation is quantified by the Abbe number, with higher values representing lower dispersion, which is in turn typically associated with lower refractive indices (Krell *et al.*, 2009a). Refractive index also varies with stress and strain (stress-optical, elasto-optic coefficients), stoichiometry, temperature (thermo-optic coefficient, dn/dT) and electric field intensity (Pockels and Kerr effects) (Harris, 1999). Non-cubic materials have different refractive indices along different directions, scattering different polarizations at every grain (birefringence) and rendering thick sections translucent. Thus, cubic (isotropic) materials are preferred. However, birefringence scattering can be greatly reduced by reducing grain size to less than $\sim 1/20$ th of transmitted wavelengths (Harris, 1999). Although this increases the number of grain intersections, birefringence scattering is decreased such that transmittance is still improved (Apetz and van Bruggen, 2003). Intrinsic birefringence in cubic single crystals due to refractive index difference along cube diagonals becomes important in the UV, but it is negligible for polycrystalline material and longer wavelengths (Krell *et al.*, 2009b).

While the reflection angle to the surface normal always equals the incidence angle (θ_i), the refraction angle (θ_r) deviates according to Snell's law; $\sin\theta_i/\sin\theta_r = v_i/v_r = n_r/n_i$, where i refers to incident and r refracted (Saleh and Teich, 1991). Reflection occurs at all interfaces bounded by different refractive indices, with non-planar or rough interfaces causing diffuse reflection and refraction (scatter). Internal scatter is caused by variations in stoichiometry and strain, secondary phases, phase transitions, cracks, pores and birefringence. It is thickness-dependent; $I_T = I_0 e^{-\alpha_{sc} t}$, where I_0 is incident and I_T transmitted intensity, α_{sc} (cm^{-1}) the scattering coefficient and t thickness (Saleh and Teich, 1991). Pores are typically the main source of scatter in transparent ceramics and scatter is maximized for pore sizes near those of transmitted wavelengths (Apetz and van Bruggen, 2003). Models, depending on scatterer sizes (Rayleigh $\ll \lambda$ and Mie $\approx \lambda$), indicate that for 5 mm-thick isotropic ceramic windows, 0.1 vol% of ~ 500 nm pores decreases in-line transmittance at $\lambda = 600$ nm to $\sim 1\%$ (55% transmittance for 0.01 vol%) (Fig. 2) (Apetz and van Bruggen, 2003). For 1–5 mm thick windows in the visible, tolerable pore-sizes are < 60 nm and concentrations < 200 ppmv and preferably < 100 ppmv ($< 1/100$ th of 1%), and likely < 5 ppmv for more demanding applications like laser media (Goldstein and Krell, 2016).

Transmittance is also attenuated by extrinsic absorption, which is caused by impurities (carbon, OH⁻), secondary phases and ions with lower bandgaps or electronic transitions (transition metals, rare earths), luminescent species, absorbing or luminescent point defects (color centers) and by free-carriers in semiconductors (Tropf *et al.*, 2000; Harris, 1999; Goldstein and Krell, 2016). Like scatter, absorption is thickness-dependent (Beer-Lambert law); $I_T = I_0 e^{-\alpha_{abs} t}$, where t is thickness and α_{abs} (cm^{-1}) the absorption coefficient. For a window with reflection losses included; $I_T \approx (1 - R_2)^2 e^{-\alpha_{abs} t}$, and if scatter is also present it can be

Fig. 2 Percent theoretical transmission as a function of porosity (P 0.01% and 0.1% [dash-dot lines]), thickness (1 mm and 5 mm [gray solid line]), wavelength (200 [dotted line], 600 and 2500 nm [dashed line]), refractive index (1.72 [spinel], 1.76 [Al₂O₃], 2.15 [c-ZrO₂], 2.50 [PLZT]) [solid lines] and total (TLT) and in-line (ILT) [dash-dot lines] transmittance calculated using a Mie model. combined with absorption in an attenuation coefficient; $I_T \approx (1 - R_2)^2 e^{-\alpha_{att} L}$, where $\alpha_{att} = \alpha_{abs} + \alpha_{sc}$ (Harris, 1999; Fox, 2001; Van Damme *et al.*, 1991; Li *et al.*, 2005). In which case it is a measure of in-line transmission since total transmittance also includes diffuse scatter. Alternatively, these variables are related by; $I_0 = I_T + I_R + I_A + I_S$, where R is reflectance, A absorbance, and S scatter. In terms of attenuation, optical elements and high-power optics typically require $\alpha_{att} < 1-0.1$ (Tropf *et al.*, 1995). Radiant emission can also obscure transmittance or saturate detectors in IR applications. It is quantified by emittance, the fraction of radiant power emitted compared to a blackbody, which is proportional to the fourth power of temperature and whose intensity and peak wavelength vary with temperature (Harris, 1999).

Transmittance, reflectance and absorbance can be determined by spectrophotometry and resolution quantified by methods like the modulation transfer function (Harris, 1999). Due to their effect on attenuation, the thickness and the measurement method should be taken into account for comparisons. The total transmitted intensity (TLT) through a window includes forward scatter and so the in-line transmittance (ILT), within a narrow cone of 3°–5°, or the real in-line transmission (RIT) within a cone of <0.5° are better representations of transmission (Krell *et al.*, 2009a). ‘Transparent’ sometimes refers to high transmittance that is nearly thickness-independent, while ‘translucent’ refers to lower values. Transparency can also be defined in terms of the absorption coefficient, for example $\alpha < 1 \text{ cm}^{-1}$ (Tropf *et al.*, 2000; Goldstein and Krell, 2016; Krell *et al.*, 2009a). Microwave transmittance is important for radomes and some IR applications and is quantified like visible transmittance, with the absorption coefficient replaced by $(2\pi/\lambda)\tan \delta$ (where $\tan \delta$ is the loss tangent) and the refractive index with the dielectric constant $\epsilon = n^2$, with higher transmittance for low dielectric constants and loss tangents (Harris, 1999).

Transparent ceramics can also exhibit special optical properties, such as total internal reflection, fluorescence (non-coherent re-emission), multi-photon absorption and re-emission at shorter wavelengths (upconversion), phosphorescence (delayed re-emission), stimulated emission with a population inversion in a resonant cavity (lasing), refractive index variation with applied voltage (electrooptic effect) or field (magneto-optic effect), and color change with applied voltage (electrochromic), temperature (thermochromic) or illumination (photochromic). Moreover, some these properties can be combined by fabricating composites or laminates (i.e., smart windows) (Goldstein and Krell, 2016; Kong *et al.*, 2015). Some of these effects are caused by nonlinear responses in frequency, polarization, phase or path, especially in the presence of high fields (i.e., lasers) and are quantified by various nonlinear optical coefficients (Tropf *et al.*, 2000). Common electro/magneto-optic effects include the linear change in refractive index with applied electric field (Pockels effect), usually described by the largest electrooptic tensor element (i.e., r_{33} or r_c [$10^{-10} \text{ m} \cdot \text{V}^{-1}$]); the nonlinear Kerr effect quantifying the change with the square of the field, expressed by the Kerr coefficient K [$\text{m} \cdot \text{V}^{-2}$] for a DC field, and the R coefficient [$10^{-16} \text{ m}^2 \text{ V}^{-2}$] and second-order nonlinear refractive index n_2 [$10^{-16} \text{ m}^2 \text{ W}^{-1}$] for an AC (optical) field; and the Verdet constant ($\text{V} [\text{rad} \cdot \text{T}^{-1} \text{ m}^{-1}]$) describing the strength of plane-polarization rotation by a magnetic field (Faraday effect) (Tropf *et al.*, 1995).

Physical Properties

Transparent ceramics exhibit a host of other sought-after mechanical, chemical, thermal, electronic and magnetic properties, which are discussed in more detail in sections on individual materials. Properties are generally assessed as for opaque ceramics, with

some methods preferred depending on the application (i.e., ring-on-ring equibiaxial flexure for window strength). Typical transmission spectra and windows for common transparent ceramics are shown in **Figs. 3** and **4**, with common non-ceramic optical materials and single crystals included for comparison. These should be used for relative comparison only as optical properties vary significantly depending on material quality and sample thickness.

General physical properties for common materials are given in **Tables 1, 2** and other materials or properties can be found in referenced texts (Tropf *et al.*, 1995; Harris, 1999; Tropf *et al.*, 2000; Weber, 2003; Kong *et al.*, 2015; Goldstein *et al.*, 2020). Common glasses and polymers are included for comparison, and less common materials with exceptional properties are included to show the full range of properties attainable. As for optical properties, caution should be exercised when making comparisons. Wherever possible data is for polycrystalline and preferably transparent material, and when known it is indicated if for coatings or single crystals. However, some mechanical and thermal properties and many optical properties (i.e., n , dn/dT) are invariably for single crystals. Physical properties vary significantly depending on testing conditions, specimen geometry and thickness, surface finish, stoichiometry, impurity content, point defects, and flaws and flaw-size distribution. This is especially true for polycrystalline material, where local variations in these properties and also grain orientation, grain size and grain-size distribution can occur. Properties like hardness, strength and toughness often increase with decreasing grain-size (Hall-Petch relation) and are significantly affected by surface finish (Harris, 1999). The figures of merit (R' for mild and R for severe) are important for aerothermal window and laser applications and provide a semiquantitative comparison of thermal shock resistance, where the larger the figure, the greater the heat flux withstood without failure (Harris, 1999).

Some general property trends emerge depending on bonding and constituent atoms. Strong covalent bonds (SiO₂) or ionic character (LiF) are typically associated with higher-energy bandgaps (thus shorter-wavelength UV absorption edges) and lower refractive indices (thus higher transmittance), but lower IR absorption edges, especially for materials with lighter constituent atoms. Strongly-bonded materials also usually have high moduli, hardness, strength and room-temperature thermal conductivity, but lower thermal expansion. Higher structural symmetry can also increase hardness and reduce the number of unique lattice vibrations, reducing IR absorption and extending the absorption edge, as in diamond (Saleh and Teich, 1991; Tropf *et al.*, 1995; Bass, 1995; Harris, 1999; Tropf *et al.*, 2000; Weber, 2003). Materials with heavier elements and weaker bonds (ZnS, KBr) typically have lower thermo-mechanical properties, but since vibrational energy increases with bond strength and decreases with increasing atomic mass, they have longer-wavelength IR absorption edges (Harris, 1999). Carbides can feature excellent thermo-mechanical properties, but lack oxidation resistance, and apart from diamond typically have low visible transparency. Oxides, nitrides and oxynitrides generally exhibit good visible and MWIR transparency and good to excellent thermo-mechanical properties and oxidation resistance. alkaline/alkaline fluorides and chlorides (CaF₂, KCl) have low UV absorption edges, refractive indices and dispersion, rendering high transmission from the UV (MgF₂) to the LWIR (BaF₂), but they tend to have lower thermo-mechanical

Fig. 4 Transmission windows for select transparent ceramics and reference materials based on >10% transmittance near absorption edges. Adapted from Harris, D.C., 1999. *Materials for Infrared Windows and Domes: Properties and Performance*. SPIE Optical Engineering Press. Values from Weber, M., 2003. *Handbook of Optical Materials*. CRC Press. Harris, D.C., 1999. *Materials for Infrared Windows and Domes: Properties and Performance*. SPIE Optical Engineering Press.

mechanical properties than oxides and can be hygroscopic (LiF) or even water-soluble (NaCl). Phosphides, sulfides, selenides, tellurides, bromides and iodides generally have lower thermo-mechanical properties and limited visible transmittance, but can have high transmittance up to the far-IR (CsI), competing with semiconductors (Si, Ge, GaAs). An important metric is cost, with some materials, like diamond and Y_2O_3 being more expensive than materials with comparable properties. A general ranking of select transparent ceramics is shown in [Table 3](#).

Processing

Processing depends on whether single crystal, bulk polycrystalline or coating material is sought ([Table 4](#)), the anion type (which can affect sintering atmosphere); properties like bonding, phase transitions, diffusion, volatility and melting point (which influence the sintering regime and the need for additives and/or pressure); and the component geometry and production scale. To ensure transparency, the goal is obtaining fully-dense, homogeneous (in phase, stoichiometry and residual stress) bodies with minimal porosity, secondary phases, impurities and absorption centers. This is a difficult prospect considering the extreme sensitivity of transparent ceramics to impurities and processing parameters. Even when transparency is attained, processing must be taken a step further than for opaque ceramics as virtually every type of defect is observable through the thickness. Although this presents a challenge, transparency enables easily finding defects to uncover their nature.

Single crystals are produced by melt-growth methods like the Czochralski process, where an oriented seed crystal is slowly pulled from a melt to produce a boule. However, extensive machining is required to obtain desired shapes. Newer methods like edge-defined film-fed growth can competitively produce sheets, windows and cylinders. Since they lack grain boundaries, single crystals are less prone to pores and secondary phases and typically have higher refractive index homogeneity ([Tropf et al., 2000](#); [Stevenson et al., 2011](#)). However, they can still have compositional and refractive index gradients and stoichiometry control can be difficult for complex systems. Moreover, processing is often slower and more expensive, geometry is limited, fewer toughening

Table 1 Optical properties of select transparent ceramics

Compound	Formula	Structure ^a	Refractive index ^b		dn/dT ^b		Transmittance			Bandgap eV	Cut-Off (μm) ^c

Materials, Engineering, and Applications. John Wiley & Sons and individual-material references.

mechanisms are available and thermo-mechanical properties are typically lower (Harris, 1999; Stevenson *et al.*, 2011). Furthermore, single crystals lack the doping flexibility and property tailoring ability of polycrystalline ceramics by microstructure modification (Tropf *et al.*, 1995; Stevenson *et al.*, 2011). Whereas, polycrystalline ceramics can be formed into complex near-net shapes at lower cost and properties can be tailored or improved by modifying grain size, composition and phase transitions, and by introducing dopants. Moreover, they typically have higher hardness, strength, fracture toughness, and thermal shock resistance, while retaining good optical properties (Stevenson *et al.*, 2011). Single crystals are typically used in applications requiring small components and/or homogeneous, directional or specialty optical properties, while polycrystals are often used when larger sizes, coatings, or better mechanical properties are required (Tropf *et al.*, 1995).

Although materials like diamond and ZnS are more easily produced by deposition, most bulk polycrystalline transparent ceramics are made by sintering powders. Research studies often cold-press and sinter dry powders, but fine powders cause dusting issues, and high frictional forces cause density gradients and require high pressing loads, limiting green-body size due to press-size limitations. Thus, bulk commercial polycrystalline transparent ceramics are usually made by traditional ceramic processing. This can consist of aqueous or solvent-based milling with ceramic media to deagglomerate powders, filtering, adding organic binders and lubricants to produce easy-to-press granules by spray- or freeze-drying, sieving, uniaxial and/or cold-isostatic pressing to form green bodies, debinding to remove organics, sintering to closed porosity, pressure-assisted sintering to remove remnant pores and annealing to restore stoichiometry. For materials like Y_2O_3 all of these steps may be used, while for others like Al_2O_3 and ALON only some are used (Harris, 1999; Savage, 1991; Mroz *et al.*, 2005).

The availability of high-purity nanometer-sized powders was one of the keys to enabling transparent ceramics. Powders are synthesized as for opaque ceramics, but they typically require higher purity, more precise stoichiometry, higher surface area and finer and/or better-defined crystallite and particle sizes and size-distributions. Such powders typically consist of high-purity (< 100–1000 ppm impurities) soft agglomerates with narrow particle-size distributions that are composed of near-spherical high surface-area nanometer-sized crystallites. Precursors often contain species not contributing to the final structure that can be completely removed after reaction (hydroxides, nitrates, carbonates, chlorides, fluorides, alkoxides, etc.). Common synthesis methods include solid-state (decomposition, chemical reaction, mechano-chemical), wet-chemical (precipitation, liquid-evaporation [spray drying, spray pyrolysis, freeze drying], gel [sol-gel, pechini, citrate, glycine-nitrate]), and gas-phase processes, with many of these requiring a calcination step (Kong *et al.*, 2015). Although the high sintering activity of nanometer-sized (< 100 nm) crystallites is desired, these tend to agglomerate during milling. Often an optimum size consisting of slightly larger crystallites or particle agglomerates is desired (Krell *et al.*, 2009a, 2003). Care must also be taken with process air and water and the purity of organic additives. More attention has also recently been given to the importance of green bodies, and increasing homogeneity can be much more effective in avoiding visible defects than attempting fixes during later steps (Krell and Klimke, 2006). In that respect, colloidal processes such as slip-, gel- and tape-casting and pressure-filtration are well-suited to achieve higher homogeneity (Jung *et al.*, 2018).

Scattering by pores is typically the main attenuating phase in polycrystalline material, and so reducing porosity often becomes the crux of fabrication. Although nanometer-sized crystallites can provide the sintering activity required to reach near-theoretical density, materials with high melting-points, covalent bonding, low diffusion and/or volatility often require additional driving forces. Sintering additives have been used since the outset and assist densification by forming liquid phases and/or increasing diffusion. Small quantities are used to avoid secondary-phase formation and/or fugitive compounds that evaporate prior to closed porosity are chosen. Although pressureless sintering is preferred to lower cost, pressure is often required to increase sintering kinetics and/or close residual pores by methods like hot-pressing (HP), hot isostatic pressing (HIP), hot-forging, gas-pressure sintering and ultra-high-pressure sintering (Oparina *et al.*, 2019). For example, MgF_2 can be made by HP, Y_2O_3 by sinter-HIP and MgAl_2O_4 by HP-HIP (Harris, 1999). Recently-introduced processes like spark-plasma sintering (SPS) and field-assisted sintering (FAST) can yield transparent specimens in minutes, but geometry is limited and they are rarely applicable to commercial production. One promising method is full-crystallization from glass precursors and other methods are continually being introduced (Goldstein and Krell, 2016; Allix *et al.*, 2012; Xiao *et al.*, 2019). Although processing to closed porosity is a difficult endeavor, the last steps in fabrication (machining, grinding and polishing) can often be the most expensive for hard materials (Harris, 1999; Patel *et al.*, 2000).

Since the advent of high-purity powders, impurity-based absorption can be virtually eliminated with careful processing. One exception is carbon-contamination from graphitic furnaces during sintering. CO_2/CO atmospheres produced at high temperatures can result in migration of carbon along boundaries and cause broad-based absorption. This can be reduced by using non-graphitic elements (i.e., MoSi_2), shielding with refractory foils or sprays, sintering in powder beds and post-annealing in air. For materials like Al_2O_3 and ZrO_2 , reducing conditions generate vacancies that act as absorbing color centers (Goldstein and Krell, 2016), which can be removed by annealing in air. Another source of absorption in the IR is -OH stretching due to adsorbed water vapor, which can be reduced by annealing in dry argon (Harris, 1999). However, annealing treatments should be used with care as they are often associated with pore growth.

Many transparent ceramics are applied as coatings (thin-films, < 100 μm thick) and to a lesser extent, claddings (thick free-standing films, > 100 μm). They are used to modify optical behavior (antireflection, anti-glare, heat-mirror, wavelength-selectivity, electromagnetic interference protection) and/or to improve mechanical or chemical behavior (strength, toughness; scratch, wear and erosion resistance; and anti-static and hydrophobic properties), or they can serve as the active layer (transparent conducting oxides) (Harris, 1999; Xie and Hintzen, 2013a; Rubat du Merac *et al.*, 2018; Dobrowolski, 1995; Lee and Kuo, 2013). Advantages include imparting required functional properties while minimizing the amount of material used and the ability to use materials that are difficult to fabricate in bulk form (i.e., diamond). Although, this is sometimes at the expense of mechanical properties.

Table 3 General ranking of select transparent ceramics

<i>Property</i>	<i>Rank</i>
<i>Optical</i>	
High Bandgap	LiF, MgF ₂ , BeO, CaF ₂ , BaF ₂ , sapphire, Al ₂ O ₃ , NaCl, (SiO ₂), MgO
Low <i>n</i> (0.6 μm)	MgF ₂ , CaF ₂ , (SiO ₂), BaF ₂ , KBr, MgAl ₂ O ₄ , BeO, MgO, Al ₂ O ₃ , AlON
High <i>n</i> (0.6 μm)	GaP, BP, SiC, ZnSe, PLZT, diamond, ZnS, ZrO ₂ , BN, AlN, Si ₃ N ₄
Low <i>dn/dT</i> (Vis.)	MgF ₂ , (SiO ₂), Y ₂ O ₃ , spinel, diamond, YSZ, YAG, CaF ₂ , Al ₂ O ₃ , BeO
Low <i>dn/dT</i> (4 μm)	MgF ₂ , AlON, sapphire, (SiO ₂), LiF, diamond
High Abbe Number	MgF ₂ , LiF, CaF ₂ , BeO, NaF, sapphire, (SiO ₂), YAG, spinel, AlON
Theo. Transmittance	LiF, MgF ₂ , CaF ₂ , (SiO ₂), NaCl, (PC), spinel, sapphire, AlON, YAG
Low UV Cut-Off	LiF, MgF ₂ , CaF ₂ , BeO, SrF ₂ , (SiO ₂), sapphire, MgO, spinel, YAG
High IR Cut-Off	diamond, (Si), CsI, CsBr, TlBr, KI, KBr, KCl, NaCl, (Ge), ZnSe
Low MWIR Cut-Off	MgF ₂ , Y ₂ O ₃ , MgO, spinel, sapphire, AlON
Low Emittance (700K)	Y ₂ O ₃ , spinel, sapphire, AlON
<i>Mechanical</i>	
Low Density	NaCl, (SiO ₂), LiF, KBr, MgF ₂ , CaF ₂ , SiC, Si ₃ N ₄ , AlN, diamond, MgO, spinel

Table 4 Typical fabrication form of select transparent ceramics

<i>Form</i>	<i>Material</i>
Single Crystal	sapphire, YAG, LiF, MgF ₂ , CaF ₂ , BaF ₂ , NaCl, KCl, KBr, SrI ₂ , CsI
Polycrystalline	MgF ₂ , ZnS, ZnSe, CaF ₂ , MgO, spinel, AlON, Y ₂ O ₃ , La-Y ₂ O ₃ , YSZ
Coating	diamond, GeC, SiC, Si ₃ N ₄ , AlN, BN, BP, GaP, ITO, ZnO, TiO ₂

Note: Harris, D.C., 1998. Durable 3–5 μm transmitting infrared window materials. Infrared Phys. Technol. 39, 185–201. Harris, D.C., 1999. Materials for Infrared Windows and Domes: Properties and Performance. SPIE Optical Engineering Press.

Coatings are commonly applied by evaporation processes (CVD and PVD), sputtering, solution-deposition methods (dip- and spin-coating) and lamination for thicker coatings. They are often associated with tensile or compressive residual stress and sometimes require an interlayer for bonding or to accommodate thermal-expansion mis-match during operation (Harris, 1999). They can consist of single or multiple layers, be continuously-graded or be made as moth-eye surfaces (Dobrowolski, 1995). Fig. 5 shows microstructures for select bulk transparent ceramics and coatings.

Applications

Transparent ceramics are used in a wide-range of applications determined by the required functional properties and property combinations (Gagliardi, 2017). Major uses include scratch-resistant windows, transparent armor, durable UV and IR windows and domes, lamp envelopes, optical elements, laser hosts, scintillators and functional thin-films (Goldstein and Krell, 2016; Kong *et al.*, 2015; Goldstein *et al.*, 2020; Xiao *et al.*, 2019). Translucent lamp envelopes for high-intensity sodium-vapor lamps were the first commercial application (Burke, 1996). These must withstand corrosive sodium vapor at high temperature and pressure, requiring sufficient

strength and chemical, thermal and thermal-shock resistance, although typically only translucency is required. Transparent ceramics are also an integral part of lighting as transparent phosphors and potentially luminescent windows in LED's (Xie *et al.*, 2013b).

Windows for scanners, machinery, outdoor lighting and consumer goods are an emerging application with significant growth potential. These require high visible transparency, moderate strength and toughness, high hardness and scratch and impact resistance. Although ceramics have significantly higher hardness and scratch-resistance than strengthened glasses, glass-ceramics and polymers, they face stiff competition due to higher cost. Transparent armor is also a growing segment that additionally requires low areal density, ballistic resistance, multi-hit capability and sometimes multi-spectral (UV-IR) transmittance (Harris, 1999). Although they can be used on their own, armor ceramics are typically part of a laminate consisting of a hard ceramic strike-face that erodes and breaks-up projectiles, and one or more layers of glass and polymer that absorb energy, increase stiffness and prevent spalling, interspersed with thermal-expansion mis-match interlayers (Patel *et al.*, 2000). Moreover, while ceramics can reduce areal density by up to 65% compared to competing materials, higher cost makes them more attractive for areal (helicopters, aircraft) applications where low weight is a greater priority (Crouch *et al.*, 2017). Aerothermal IR windows and domes additionally require low thermal expansion and emissivity, high thermal diffusivity and erosion and thermal-shock resistance, a combination few materials can match (Harris, 1999). Sight-glasses for thermal and chemical processes are a niche application also requiring chemical and thermal resistance.

Table 5 Typical wavelength-range and application of common transparent ceramics

Range/Sector	Common ceramics [Potential in brackets]
UV materials	CaF ₂ , sapphire, KBr, [BeO, LiF, MgF ₂ , MgO, spinel]
Vis/armor materials	sapphire, spinel, AlON, [YSZ, YAG, diamond]
MWIR materials	Y ₂ O ₃ , AlON, spinel, MgF ₂ , ZnS, ZnSe, Al ₂ O ₃ , sapphire, KBr, BP
LWIR materials	MgF ₂ , CaF ₂ , ZnS, ZnSe, GaP, diamond, [MgO]
Laser hosts	YAG, Y ₂ O ₃ , ZnSe, ZnS, [Sc ₂ O ₃ , La ₂ O ₃ , LuAG, LiF, CaF ₂ , SrF ₂]
Scintillators	(Y,Gd,Eu) ₂ O ₃ , Gd ₃ Ga ₅ O ₁₂ , YAG, LuAG, SrI ₂ , [many potential]
Lighting	Al ₂ O ₃ , GaN, GaP, YAG, [sapphire, MgAl ₂ O ₄ , Y ₂ O ₃ -La ₂ O ₃ , AlON]

Laser hosts are another early application and ceramics are now the leading solid-state laser material (Hatch *et al.*, 1964; Goldstein and Krell, 2016). Hosts are the material to which rare-earth or transition-metal dopants are added to result in stimulated emission and gain when optically-pumped within an optical resonator made by (partially) mirroring ends. In addition to properties required for IR windows and domes, laser hosts require lower absorption/defect concentrations, low dn/dT and the ability to uniformly incorporate active dopants. Moreover, they must withstand high thermal energy gradients and radiation damage (Goldstein and Krell, 2016; Kong *et al.*, 2015; Sanghera *et al.*, 2012). Scintillators have similar requirements regarding dopants and must be transparent while allowing radiation of emitted photons. Moreover, they require high absorption (X-ray or gamma-ray stopping power) and re-emission (light yield) cross-sections that are proportional to detected radiation, short decay times, tolerance to radiation damage and good mechanical properties (Cherepy *et al.*, 2007; Greskovich and Duclos, 1997).

UV–vis–IR optical elements were also early applications that still employ a wide variety of single-crystal and polycrystalline materials (Goldstein *et al.*, 2020; Stevenson *et al.*, 2011). Special optical properties like low or high refractive index, low dispersion, UV or IR transmittance, luminescence and nonlinear optical behavior are necessary for many optical elements (lenses, prisms, beamsplitters, mirrors, nonlinear and wave-mixing crystals, acoustooptical and polarization devices and interference filters). Moreover, electro- and magneto-optical properties are needed to enable technologies like touchscreens, sensors, photovoltaics and smart windows. Hard, scratch-resistant coatings, with antireflective, heat-mirror, solar-selective or other functional properties are another important application (Goldstein *et al.*, 2020; Xie and Hintzen, 2013a). Transparent ceramics have also been used in luxury goods such as watches and as artificial gemstones. Cost is a driving factor for many applications, with competition from single crystals, glasses, glass-ceramics and polymers.

With the advent of new materials and advanced processing, new applications are continually emerging. For example, the lowest UV absorption edge of known optical materials combined with low intrinsic birefringence could enable UV lithography windows and optics for the next-generation of microprocessors (Burnett *et al.*, 2005). Common materials used in select applications are summarized in Table 5. Applications are described in more detail in the sections on individual materials and in referenced articles.

Materials

There are hundreds of transparent ceramic compounds and new ones are continually being added, so only more common materials are described in detail. Moreover, the emphasis is on materials that are well-developed, commercially-available and/or have commercial/military relevance. Although, some newly-developed and less common materials with exceptional properties are described to show the full-range of attainable properties. Many materials that are not described because they occupy small niche applications can nevertheless be essential in enabling those applications, and more exhaustive treatments are found in optical materials references (Tropf *et al.*, 1995; Harris, 1999; Tropf *et al.*, 2000; Weber, 2003; Sanghera *et al.*, 2012; Xie and Hintzen, 2013a; Kong *et al.*, 2015; Xiao *et al.*, 2019). Figs. 6 and 7 give an overview of the range and appearance of common transparent ceramics. Oxides constitute the vast majority by market share, mainly Al₂O₃, yttrium aluminum garnet (YAG) and MgAl₂O₄, and these are described in greater detail. Materials are loosely-grouped by anion group (carbides, nitrides, phosphides, oxides, oxynitrides, other chalcogenides, fluorides, other halogens) and their order in the periodic table, structure (perovskite, pyrochlore), application (conducting oxides, ferroelectrics) and form (nanocomposites, coatings) in order to combine materials with similar properties and/or applications.

Carbides

Carbides can feature transparency combined with extreme physical properties. Strong covalent bonds confer the highest strength, stiffness, hardness and thermal conductivity of known optical materials (Harris, 1999). However, covalent bonding, polymorphism

and high melting temperatures pose significant processing challenges. As such, carbides are mainly used as thin-coatings, with diamond and SiC being common. However, many other carbides (GeC [germanium-carbon], TaC, etc.) are used in niche applications and some like BC are still being developed (Monaghan *et al.*, 1992; Hu *et al.*, 2006; Mondal *et al.*, 2015).

Diamond

Diamond is in a class by itself with its extraordinary physical properties. It has an exceptionally-wide transmission window (250 nm to $>100\ \mu\text{m}$), low dn/dT ($\sim 10 \times 10^{-6}\text{K}^{-1}$ at 600 nm) and a low dielectric constant (ϵ 5.7) (Tropf *et al.*, 1995; Harris, 1999). Diamond features the highest hardness ($9000\ \text{kg}\cdot\text{mm}^{-2}$) and stiffness (1143 GPa) of known materials, excellent fracture toughness

($K_{IC} \sim 5.3 \text{ MPa}^{-1/2}$), extreme scratch and erosion resistance, high strength (200–1000 MPa), low thermal expansion ($0.8 \times 10^{-6} \text{ K}^{-1}$), the highest room temperature thermal conductivity of any known material ($2000 \text{ W} \cdot \text{m}^{-1} \text{ K}^{-1}$ at 25°C) and outstanding thermal shock resistance ($R' 410 \text{ kW} \cdot \text{m}^{-1}$) (values for CVD diamond) (Tropf *et al.*, 1995; Harris, 1999, 2002). However, it can't be used in the MWIR due to absorption from 3 to $5 \mu\text{m}$, its high refractive index ($n 2.4$) limits theoretical transmittance ($< 70\%$), it oxidizes above 700°C if uncoated and graphitizes above 1500°C , and grinding and polishing costs are high due the high hardness (Goela, 1998; Harris, 1999). Diamond's exceptional properties make it a candidate for strong, tough, multi-spectral (Vis–UV–IR–MW) windows; scratch-, wear- and chemical-resistant windows or components; the ultimate laser window (the preferred material for CO₂ lasers) and laser host, and heat-sink substrates for electronics. Although industrial diamond is made as small single crystals by high-pressure high-temperature growth, transparent polycrystalline material is made by plasma-CVD substrate growth in H₂ atmosphere (Harris, 1999, 2002). Processing is made difficult by the high temperature/pressure required and contamination (i.e., nitrogen and boron) (Savage, 1991). CVD diamond is currently thickness-limited, contains internal flaws and exhibits light-scattering at grain boundaries. Although thin windows several centimeters across and domes up to 1 mm thick have been produced, larger and thicker optical quality diamond is still being developed and it remains one of the most expensive optical materials (Harris, 1999, 2002).

Silicon carbide

Silicon carbide (SiC) has hundreds of polytypes, the most common being hexagonal α -SiC forming above ~ 1700 – 2000°C and β -SiC forming below (Kimoto and Cooper, 2014). β -SiC is of great interest due to its diamond-like properties. It has a cubic zincblende structure, high refractive index ($n 2.6$ at 633 nm), low density ($3.21 \text{ g} \cdot \text{cm}^{-3}$), moderately high strength (300–828 MPa); high fracture toughness ($K_{IC} 2$ – $6 \text{ MPa} \cdot \text{m}^{1/2}$), hardness (up to 25 GPa) and stiffness (310–500 GPa); high-temperature resistance (sublimes > 1800 – 2000°C), unlike diamond high oxidation resistance, low thermal expansion ($4 \times 10^{-6} \text{ K}^{-1}$), outstanding thermal conductivity (up to $490 \text{ W} \cdot \text{m}^{-1} \text{ K}^{-1}$ at 300 K) and thermal shock resistance ($R 12 \times 10^3 \text{ K}$) and chemical inertness. It's a

semiconductor with high electric field breakdown strength ($2.1 \text{ MV} \cdot \text{cm}^{-1}$), maximum current density and electron mobility ($800\text{--}1000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$), and electroluminescence properties (Goela, 1998; Gerhardt, 2011; Kimoto and Cooper, 2014). However, it is only transparent from $\sim 0.5\text{--}5.0 \text{ }\mu\text{m}$, has low impact resistance, high emittance between $4\text{--}5 \text{ }\mu\text{m}$ and transparent material is still being developed (Gerhardt, 2011; Bayya *et al.*, 2013; Naftaly *et al.*, 2016). First made by carbothermic reduction of SiO_2 in an Acheson furnace, transparent single crystals are made using the Lely method and polycrystalline material has been made by CVD, HP, reaction-bonding and SPS (Goela, 1998; Bayya *et al.*, 2013; Kimoto and Cooper, 2014). Applications include the first commercial LED, UV-detectors, diamond gemstone simulants, lightweight mirrors; hard, scratch-resistant anti-reflective coatings (especially for silicon photovoltaics); and potentially transparent armor, aerothermal windows and heat-sink laser windows (Harris, 1999; Bayya *et al.*, 2013; Kimoto and Cooper, 2014).

Nitrides

Nitrides share similarities with oxides and can feature exceptional hardness and fracture toughness, high strength and wear resistance, chemical and thermal stability, outstanding thermal conductivity, and interesting semiconducting, optoelectronic and luminescent properties. However, covalent bonding and high melting points complicate processing, and development and achieved transmittances have lagged that of oxides. Densification typically requires additives and liquid-phase sintering in N_2 atmosphere. Silicon nitride is a common antireflection coating material, while SiAlONs and aluminum nitride are being developed for their unique functional properties. Moderate refractive indices combined with excellent mechanical properties enable use as thin-film antireflection (Si_3N_4), surface passivation (Si_3N_4 , AlN, TiN, ZrN), heat-mirror (TiN, ZrN) and absorbing solar-selective coatings. Moreover, photoluminescent properties (GaN, AlN, BN, SiAlONs) are sought for phosphors and LED's, with many other potential applications (transparent armor, windows, transparent conductors, optoelectronic devices) likely to arise (Xie and Hintzen, 2013a).

Silicon nitride

Silicon nitride (Si_3N_4) occurs as trigonal α - Si_3N_4 , higher-temperature hexagonal β - Si_3N_4 and a high-pressure cubic spinel γ - Si_3N_4 (or c - Si_3N_4) polymorph. The α and β polymorphs exhibit exceptional hardness (up to 22 GPa) and fracture toughness (K_{IC} up to $7.2 \text{ MPa} \cdot \text{m}^{1/2}$) combined with moderate density ($3.24 \text{ g} \cdot \text{cm}^{-3}$) and a wide bandgap (5.3 eV) with potential transparency from the visible to the SWIR, but they have relatively high refractive indices (n 2.1 at 600 nm) and are translucent due to birefringence (Harris, 1999; Xie and Hintzen, 2013a; Yang *et al.*, 2013; Li *et al.*, 2015). Nevertheless, translucent β - Si_3N_4 has been made by methods like HP and SPS, typically with sintering additives (Xiao *et al.*, 2019). Si_3N_4 is also made by CVD, typically as amorphous hydrated (SiN_xH) material for transparent antireflective coatings for solar cells (Xie and Hintzen, 2013a). c - Si_3N_4 has higher density ($4.08 \text{ g} \cdot \text{cm}^{-3}$), but exceptional stiffness (583 GPa) and hardness (HV 34.9 GPa), high fracture toughness (K_{IC} $3.5 \text{ MPa} \cdot \text{m}^{-1/2}$) and high thermal resistance in air (up to 1400°C). However, only small samples with visible transmittance of 18%–38% have been made by high-pressure (13 GPa) synthesis (Nishiyama *et al.*, 2017). If successfully developed, c - Si_3N_4 would make an excellent candidate for aerothermal windows operating in harsh environments in the $0.5\text{--}4 \text{ }\mu\text{m}$ range (Xiao *et al.*, 2019).

SiAlON

SiAlONs are isostructural Si_3N_4 solid-solutions with the hexagonal β - Si_3N_4 structure stabilized by replacing Si and N with Al and O, and the trigonal α structure stabilized by replacing Si with Li, Mg, Ca, Sc, Y and most rare earths (Jack, 1976; Cao and Metselaar, 1990; Mandal, 1999), with the wide-variety of dopants allowing property tailoring. In spite of birefringence, SiAlONs feature promising properties including high strength (up to 1000 MPa) even at temperature, high hardness (up to 21 GPa), exceptional fracture toughness (K_{IC} up to $8 \text{ MPa} \cdot \text{m}^{1/2}$), low friction coefficient and high wear resistance, high-temperature and thermal-shock resistance, low thermal expansion, outstanding corrosion resistance and good oxidation resistance $<1000^\circ\text{C}$ (Cao and Metselaar, 1990; Mandal, 1999; Jones *et al.*, 2003; Xiong *et al.*, 2008). Although visible transmittance is low ($\sim 70\%$ Lu-doped), IR transmittance is usually higher, and up- (Er^{3+} , Tm^{3+}) and down-conversion (Eu^{3+}) luminescence has been demonstrated (Xie and Hintzen, 2013a; Joshi *et al.*, 2015; Xiao *et al.*, 2019). α -SiAlON typically has equiaxed grains and higher hardness, while β -SiAlON features elongated grains and better toughness (Cao and Metselaar, 1990; Mandal, 1999). Translucent/transparent material has been made by gas-pressure sintering, HP, HIP and SPS in N_2 atmosphere, sometimes by transient liquid-phase sintering (Mitomo *et al.*, 1982; Cao and Metselaar, 1990; Jones *et al.*, 2003, 2004; Xie and Hintzen, 2013a). Transparent SiAlONs are emerging materials that have potential as luminescent up/down converting materials, phosphors and hard antireflecting films (Liu *et al.*, 2013; Joshi *et al.*, 2015; Kshetri *et al.*, 2016; Xiao *et al.*, 2019).

AlN

Aluminum nitride (AlN) has high temperature stability (T_{M} $2200\text{--}3000^\circ\text{C}$ [inert atm.], T_{D} $\sim 1800^\circ\text{C}$), good oxidation resistance due to oxide-layer formation, outstanding thermal conductivity ($320 \text{ W} \cdot \text{m}^{-1} \text{K}^{-1}$) for an insulator (ρ $10^{11}\text{--}10^{13} \text{ }\Omega \cdot \text{cm}$), a high breakdown field strength, and it exhibits piezoelectricity and luminescence (Harris, 1999; Inoue *et al.*, 2009; Xie and Hintzen, 2013a; Ioffe Database, 2020). In addition to its use as heat-sink substrates, it is of interest for applications in optics, lighting, electronics and renewable energy (Harris, 1999; Xie and Hintzen, 2013a). Although it has a high refractive index (2.02 at 600 nm) and hexagonal structure, the wide bandgap (6.2 eV) should enable visible transparency (Xie and Hintzen, 2013a; Ioffe Database,

2020). However, only poor transmittance has been achieved, with translucent (up to 77% at 800 nm) material made by sintering, HP and SPS with calcium-based sintering additives (Honma *et al.*, 2008; Xiong *et al.*, 2008; Xie and Hintzen, 2013a).

c-BN

Cubic boron nitride (c-BN) has a cubic structure and extraordinary properties, including low density ($2.51 \text{ g} \cdot \text{cm}^{-3}$); exceptional hardness ($\text{HV} > 45 \text{ GPa}$), fracture toughness ($K_{\text{IC}} > 12 \text{ MPa} \cdot \text{m}^{1/2}$) and thermal conductivity ($760 \text{ W} \cdot \text{m}^{-1}\text{K}^{-1}$); high temperature resistance ($T_{\text{M}} > 2950^\circ\text{C}$ [inert atm.]) and potential for transparency from the visible to the MWIR (Weber, 2003; Tian *et al.*, 2013; Hushur *et al.*, 2016). However, only tiny transparent samples have so far been made by high-pressure high-temperature synthesis. It is nevertheless a promising material should fabrication issues be solved.

Phosphides

Phosphides can feature wide transmission windows combined with outstanding thermo-mechanical properties. Boron phosphide (BP) has a cubic zincblende structure and IR transparency to at least $25 \mu\text{m}$, high modulus (830 MPa), exceptional hardness (up to 59 GPa [CVD]) and erosion resistance, chemical inertness and outstanding thermal conductivity ($460 \text{ W} \cdot \text{m}^{-1}\text{K}^{-1}$ at 300K [single crystal]) (Gibson *et al.*, 1994; Harris, 1999; Kang *et al.*, 2017). However, it has limited visible transmittance, the high refractive index (n 2.8 at 633 nm) limits transmittance ($< 60\%$ in the IR) and it exhibits absorption above $12 \mu\text{m}$ (Gibson *et al.*, 1994; Harris, 1999). Fabrication is complicated by the different reactivities of boron and phosphorous and although made as single-crystals and polycrystalline films, it is commonly deposited as amorphous hydrogen-containing CVD films to protect LWIR materials (Harris, 1999). Gallium phosphide (GaP) has similar properties with some transmission in the visible and up to $9 \mu\text{m}$ in the IR with higher transmittance than BP (70% IR) (Gibson *et al.*, 1994). It has good erosion and thermal shock resistance (R' 11.5) and high thermal conductivity ($97 \text{ W} \cdot \text{m}^{-1}\text{K}^{-1}$), but also much higher density ($4.13 \text{ g} \cdot \text{cm}^{-3}$) and only moderate hardness and fracture toughness (Savage, 1991; Monachan *et al.*, 1992; Gibson *et al.*, 1994; Harris, 1999). It is also deposited as protective IR films, while single crystals are used in LED's. Other phosphides, such as AlGaP, have been reported, but applications are currently limited to antireflective and/or erosion-resistant coatings (Harris, 1999).

Oxides

Oxides are the most widely-used and technologically-mature transparent ceramics. Oxygen bonding confers high strength and hardness, chemical stability, oxidation and thermal resistance, often relatively low refractive indices (n 1.56 for $\alpha\text{-SiO}_2$ at 633 nm), excellent transmission from the UV/Vis to the NIR/MWIR and relative ease of synthesis and fabrication in spite of high melting temperatures (Tropf *et al.*, 1995). However, the relatively light oxygen anion and strong bonds limit transmission in the LWIR (Harris, 1999). Oxides are typically classified as binary (BeO , MgO , ZrO_2), sesquioxides (Al_2O_3 , Y_2O_3 , Sc_2O_3 , Lu_2O_3) and multi-cation/anion species (spinel, garnets, pyrochlores, perovskites, silicates, apatites, etc.), which are grouped separately along with materials with unique properties (conducting oxides, ferroelectrics).

Binary oxides

Beryllia

Beryllia (BeO) has a low refractive index (n 1.72 at 600 nm), a very wide bandgap (10.7 eV) conferring an exceptional transmission window ($120 \text{ nm} - 9 \mu\text{m}$, MW), high resistivity ($\rho > 10^{15} \Omega \cdot \text{cm}$), low density ($3.01 \text{ g} \cdot \text{cm}^{-3}$), good mechanical properties ($E \sim 350 \text{ GPa}$, σ 180–250 MPa); thermal ($T_{\text{M}} \sim 2500^\circ\text{C}$), chemical and radiation resistance; outstanding thermal conductivity ($250\text{--}330 \text{ W} \cdot \text{m}^{-1}\text{K}^{-1}$) for an insulator, and piezoelectric and pyroelectric behavior (Budnikov and Belyaev, 1960; Harris, 1999; Kiido *et al.*, 2003; Ivanovskii *et al.*, 2009; Akishin *et al.*, 2009). However, it is toxic and the stable hexagonal $\alpha\text{-BeO}$ polymorph is birefringent and reacts with water above 830°C (Akishin *et al.*, 2009). Transparent polycrystalline BeO has been made by HP and deposition methods, but finds limited application due to toxicity. Actual/potential applications include lightweight UV-IR windows, electronic substrate heat-sinks, ballistic missile domes, microwave furnace windows, UV-emitters, UV-MWIR laser components, transparent mirror coatings, dosimetry scintillators, lamp envelopes and hollow dielectric waveguides (Kiido *et al.*, 2003; Goldstein and Krell, 2016).

Magnesia

Magnesia (MgO) has a cubic structure, relatively low refractive index (n 1.74 at 600 nm), the potential for high transmittance from 0.2 to $9 \mu\text{m}$ (87% theoretical at 600 nm), low density ($3.58 \text{ g} \cdot \text{cm}^{-3}$), good mechanical properties, and high thermal resistance ($T_{\text{M}} 2850^\circ\text{C}$) and thermal conductivity ($47\text{--}53 \text{ W} \cdot \text{m}^{-1}\text{K}^{-1}$ at 54°C) (Weber, 2003; Itatani *et al.*, 2006; Hutzler and Krell, 2013). Transparent MgO has been fabricated by pressureless sintering in air and vacuum with and without additives (LiF being common), HP, sinter-HIP and SPS (Chen *et al.*, 2008). However, processing is complicated by the high melting point and MgO volatility, and until recently only small samples with moderate transparency have been achieved despite a significant development history (Hutzler and Krell, 2013; Kong *et al.*, 2015). When larger and/or more transparent material become available, MgO will likely be considered for applications requiring high temperatures and/or thermal diffusivity.

Zirconia

Zirconia (ZrO_2) has exceptional toughness, high thermal resistance (T_M 2715°C), low thermal conductivity, high oxygen diffusivity, a high dielectric constant and a higher refractive index (n 2.17) than achievable with common glasses (Kong *et al.*, 2015). These attributes make it a candidate for tough transparent windows, miniaturized lenses and artificial gemstones. However, it has high density (5.89 g·cm⁻³) and without anti-reflective coatings the high refractive index decreases transmittance (Rubat du Merac *et al.*, 2018). Zirconia undergoes a cubic→tetragonal→monoclinic phase transition upon cooling (Hannink *et al.*, 2000; Simeone *et al.*, 2003). Substitution of aliovalent cations on Zr^{4+} sites stabilizes the desirable cubic phase by generating oxygen vacancies (Barsoum, 2003). The most typical is Y^{3+} (yttria-stabilized zirconia, YSZ), but Mg^{2+} , Ca^{2+} and $\text{Ce}^{3/4+}$ are also used. Greater than 8 wt% yttria fully-stabilizes the cubic phase (*c*-YSZ), 3%–7% results in cubic and tetragonal (partially-stabilized zirconia, PSZ) and <3% is tetragonal (*t*-YSZ) (Scott, 1975; Standard and Sorrell, 1998; Hannink *et al.*, 2000). Zirconia is the only commercial ceramic exploiting transformation toughening, where volume expansion from the metastable *t*→*m* transition counteracts crack-opening. Thus, a trade-off exists with *t*-YSZ having higher strength (>900 MPa vs <600 MPa) and toughness (8 MPa^{-1/2} vs 2.8 MPa^{-1/2}) than *c*-YSZ, but lower transmittance due to birefringence (Krell *et al.*, 2009b; Kong *et al.*, 2015). However, transparency can be improved by reducing grain-size or magnetically-aligning crystallites during green-body formation (Goldstein and Krell, 2016). Transparent *c*-YSZ has been made by pressureless sintering, HP, sinter-HIP, SPS, and multi-step sintering among others, with TiO_2 commonly used to enhance densification and impart transparency (Wang *et al.*, 2013). Transparent *t*-YSZ has been fabricated by pressureless-sinter-HIP and SPS (Kong *et al.*, 2015). Dissociated uncharged oxygen vacancies caused by processing in reducing atmospheres can render zirconia dark black, requiring post-annealing in oxygen to restore transparency (Janek and Korte, 1999). Despite promising properties, transparent zirconia has so far found limited application, for example as high-index lenses (with 68% transmittance at 0.6 μm) and artificial gemstones (Goldstein and Krell, 2016).

Sesquioxides

Alumina

Alumina (Al_2O_3) was the first synthetic transparent ceramic material and laser host as single-crystal ruby ($\text{Cr}:\text{Al}_2\text{O}_3$), the most technologically-mature and widely-used as single-crystal sapphire and the first commercial polycrystalline transparent ceramic (Lucalox®) (Patel *et al.*, 2000; Goldstein and Krell, 2016; Gagliardi, 2017; Evans, 2020). The development of sapphire spurred advances in crystal-growth, while that of polycrystalline alumina for use as high-pressure sodium-vapor lamp envelopes in the late 1950s increased the understanding of how sintering aids restrict grain-growth to avoid pore occlusion (Burke, 1996). Alumina has several polymorphs, including disordered cubic $\gamma\text{-Al}_2\text{O}_3$ and thermodynamically-stable hexagonal $\alpha\text{-Al}_2\text{O}_3$. It features high transmittance (86% at 600 nm) from the UV to the MWIR (~0.35–6 μm; polycrystalline), high strength even at temperature (up to ~1000 MPa; single crystal), exceptional hardness (>20 GPa; polycrystalline); high wear, erosion and scratch resistance; relatively high fracture toughness; excellent chemical, thermal (T_M 2072°C), thermal-shock and radiation resistance; and high resistivity (Harris, 1999; Savage, 1991; Krell *et al.*, 2004; Dobrovinskaya *et al.*, 2009; Kong *et al.*, 2015). $\alpha\text{-Al}_2\text{O}_3$ is birefringent, causing optical distortion for curved-geometry sapphire and rendering polycrystalline components thicker than a few hundred microns translucent or opaque. Sapphire windows aligned perpendicular to the *c*-axis have equivalent in-plane refractive indices, imparting near-isotropic behavior. Whereas for polycrystals, birefringence can be offset by reducing grain-size below that of transmitted wavelengths or by magnetically-aligning crystallites along the *c*-axis during green-body formation (Liu *et al.*, 2015). Decreasing grain size also increases hardness (up to 22 GPa) and strength (up to 600–800 MPa) (Goldstein and Krell, 2016; Kong *et al.*, 2015). However, even with fine grains, transparency is still far below that of sapphire and other cubic transparent materials (~<60% at 600 nm). Although, IR transmittance can be much higher if wavelengths are much larger than grain size.

Sapphire was first made using the Verneuil method, and later by methods like Czochralski, Kyropoulos, heat-exchanger, gradient-solidification, and horizontal directed-solidification, which are relatively slow, expensive and require machining components from boules (Maiman, 1960; Goldstein and Krell, 2016; Kurlow, 2016). Windows (up to 30 × 200 cm) and cylinders are now made by methods like edge-defined film-fed growth, non-capillary shaping, element-of-shape growth and variable-shaping technique (Goldstein and Krell, 2016; Saint-Gobain, 2020). Sapphire's lower manufacturing costs through industries of scale and near-net shape pit it against polycrystalline ceramics. Excellent optical properties, high strength and photochemical resistance make it an attractive laser host, with laser quality Cr^{3+} and Ti^{3+} -doped sapphire commercially-available (Savage, 1991; Dobrovinskaya *et al.*, 2009). Sapphire is used as scratch-resistant windows (watch faces, scanners), Vis-IR windows and domes, transparent armor, optical elements, laser hosts, scintillators, electronic substrates, artificial gemstones, wear-resistant bearings and components, fiber reinforcement, pressure sensors, insulators, chemical ware and medical implants (Dobrovinskaya *et al.*, 2009; Kurlow, 2016). However, it is difficult to machine and is susceptible to chipping and its hardness increases polishing costs (Bernard-Granger *et al.*, 2011). Although raw materials are relatively inexpensive, single crystals are expensive to manufacture and have limited toughening mechanisms (Harris, 1999; Bernard-Granger *et al.*, 2011). Polycrystalline alumina was initially made by high-temperature sintering in H_2 with MgO sintering additive. It has since been made using various green-body forming methods (cold-pressing, CIP, float-packing, injection molding; gel-, tape- and slip-casting, etc.) combined with methods such as two-step sintering, sinter forging, sinter-HIP, SPS, and microwave sintering, with recent emphasis on grain-size reduction using additives (Kwon *et al.*, 1995; Kong *et al.*, 2015). Applications include envelopes for high-pressure metal halide lamps, scratch-resistant windows and thin-coatings, and IR windows and domes (Harris, 1999; Goldstein and Krell, 2016).

Yttria

Yttria (Y_2O_3) has excellent transmission from the visible to the MWIR (0.2–8.0 μm , >80% up to 7 μm , even at elevated temperature), low emittance, good mechanical properties, excellent corrosion and heat resistance (T_M 2430°C), good thermal conductivity (13.6 $\text{W} \cdot \text{m}^{-1}\text{K}^{-1}$ at 300K) and lower thermal expansion ($6\text{--}7 \times 10^{-6}\text{K}^{-1}$) than YAG ($7.8 \times 10^{-6}\text{K}^{-1}$) (Hogan *et al.*, 2004; Kong *et al.*, 2015). These qualities make it a candidate for laser hosts and scintillators and IR aerothermal domes and windows. The first ceramic scintillator was made from the related compound $\text{Eu}^{3+}:\text{Y}_{1.34}\text{Gd}_{0.60}\text{Eu}_{0.06}\text{O}_3$ and the second ceramic laser was made from $\text{Nd}^{3+}:\text{ThO}_2(10\%)\text{-Y}_2\text{O}_3$ (Greskovich and Duclos, 1997; Sanghera *et al.*, 2012). The high effective atomic number and density (5.01 $\text{g} \cdot \text{cm}^{-3}$) are attractive for scintillators, but along with yttria's relatively low thermal-shock resistance and higher cost, they are a disadvantage for aerospace applications. Yttria's high melting point requires exceptionally high sintering temperatures and transparency was first achieved ~50 years ago by sintering >2000°C using up to 10 wt% ThO_2 . Transparent yttria has since been made by sintering without additives, two-step sintering, HP, sinter-HIP, SPS, and microwave sintering (Hogan *et al.*, 2004; Jin *et al.*, 2010; Kong *et al.*, 2015). Other additives (La_2O_3 , HfO_2 , ZrO_2 , BeO , LiF , and Al_2O_3) have been used to aid sintering or to improve properties (Jung *et al.*, 2018). La_2O_3 addition exploits polymorphism that restricts grain-growth at higher temperature and the mix of cubic and hexagonal phases after sintering are converted to cubic by annealing. La_2O_3 -doping increases visible transmittance and room-temperature strength, but decreases thermal conductivity and high-temperature resistance (Goldstein and Krell, 2016). Grain-size reduction using colloidal processing and SPS or microwave sintering offer further promise to increase mechanical properties. Yttria has been used or considered for IR windows and domes for missiles, laser hosts (Eu-doped), scintillators and NIR-upconverters (rare-earth co-doped) (Kong *et al.*, 2015).

Other sesquioxides

Scandia (Sc_2O_3) and lutetia (Lu_2O_3) have recently garnered considerable interest due to favorable properties. Scandia has a cubic crystal structure with high transmittance, refractive index (n 2.0 at 300 nm) and bandgap (5.7 eV); low UV cut-off (215 nm), good mechanical properties, high melting point (T_M 2430°C), good thermal conductivity (17 $\text{W} \cdot \text{m}^{-1}\text{K}^{-1}$) and chemical resistance. These properties are attractive for damage-resistant high-reflection material in LED's, high-power UV laser components, IR windows and domes and heat-resistant optical windows (Kong *et al.*, 2015). Like other sesquioxides, scandia can accommodate high doping levels of active rare-earth ions, making it attractive for laser hosts (Tm^{3+} doped). However, Sc_2O_3 , Lu_2O_3 and Y_2O_3 have relatively high non-linear refractive indices, which can cause beam distortion at high radiation intensities (Sanghera *et al.*, 2012). Highly-transparent material is commonly made by vacuum sintering with post-HIP, although it is not yet commercially-available (Kong *et al.*, 2015). Lutetia (Lu_2O_3) features a wide bandgap, good mechanical properties, low thermal expansion, high thermal conductivity and chemical stability. Its high density (9.42 $\text{g} \cdot \text{cm}^{-3}$) and atomic mass confer stopping power for ionizing radiation in scintillators, while the ability to accommodate large concentrations of Yb^{3+} ions make it an attractive laser host. Transparent Lu_2O_3 ceramics have been made by vacuum sintering, HIP and SPS. Although Eu, Nd, and Yb-doped Lu_2O_3 show promise for scintillators and have been manufactured for lasers, they are relatively expensive (Kong *et al.*, 2015; Furuse and Yasuhara, 2017; Xiao *et al.*, 2019). Sesquioxides also have promising magneto-optical properties for isolators and Faraday rotators in high-power lasers. Terbium oxide (Tb_2O_3) and holmium oxide (Ho_2O_3) have Verdet constants of 128 and 45 $\text{rad} \cdot \text{T}^{-1}\text{m}^{-1}$ at 1064 nm, respectively, comparable or higher than for terbium aluminum garnet (TAG, 47 $\text{rad} \cdot \text{T}^{-1}\text{m}^{-1}$) and terbium gallium garnet (TGG, 35 $\text{rad} \cdot \text{T}^{-1}\text{m}^{-1}$, the most common magneto-optic material for high-power lasers) (Furuse and Yasuhara, 2017; Snetkov *et al.*, 2016). Moreover, dysprosium oxide (Dy_2O_3) has a Verdet constant of 300 $\text{rad} \cdot \text{T}^{-1}\text{m}^{-1}$ at 633 nm, more than twice that of TGG at that wavelength (Furuse and Yasuhara, 2017). Scintillators based on Gd_2O_3 have also been successfully fabricated (Zeeman *et al.*, 1995).

Complex oxides

Spinel (MgAl_2O_4)

Magnesium aluminate (MgAl_2O_4 , spinel) is the only intermediate compound of the $\text{MgO-Al}_2\text{O}_3$ system and the archetype for the cubic spinel structure. It has excellent transmission from the UV to the MWIR (up to 87% at ~600 nm, also MW transparency), relatively-low refractive index (n 1.71 at 532 nm) and density (3.58 $\text{g} \cdot \text{cm}^{-3}$), slightly lower strength (~200 MPa) and hardness (16 HV) than Al_2O_3 , high-temperature resistance (T_M 2105°C) and good thermal conductivity (Rubat du Merac *et al.*, 2013; Goldstein and Krell, 2016). The slightly higher IR absorption edge than ALON and sapphire, combined with ease of manufacture and lower polishing cost makes spinel competitive for hard, scratch- and impact-resistant Vis-IR windows (Harris, 1999). Moreover, the low UV absorption edge offers potential for UV windows and optics, while the low Abbe number is interesting for lenses (Burnett *et al.*, 2005; Rubat du Merac *et al.*, 2013). Although a line compound at equilibrium, the spinel phase spans 38–90 mol% Al_2O_3 at higher temperature, and 50 to ~80 mol% can be cooled without constituent precipitation. Stoichiometry affects most properties of spinel, and although it is difficult to control partly due to MgO vaporization during sintering, it offers the potential to tailor properties (Rubat du Merac *et al.*, 2013). Transparent material was first produced over 50 years ago by pressureless sintering pressed compacts in H_2 with Li_2O and SiO_2 additives (Gatti, 1969). Since then, green bodies have been formed by cold pressing, CIP and slip-, gel- and tape-casting, and densified by HP-HIP with LiF , pressureless sinter-HIP without additives, SPS, microwave sintering and others, sometimes combined with reactive sintering (Rubat du Merac *et al.*, 2013). Windows up to 48 × 48 cm, or larger by diffusion edge-bonding smaller panes, have been made (Destefani, 2013). Although

many sintering additives have been used, the trend is avoiding them and emphasis has been on grain-size reduction. Spinel has been used as transparent armor for military vehicles, multi-spectral (Vis-IR) windows and domes; scratch-resistant windows for outdoor, consumer goods, and scanners; temperature and chemical-resistant windows and Q-switches, and it is being considered for UV and laser applications (Rubat du Merac *et al.*, 2013). Other transparent spinels like ZnAl_2O_4 have also recently been investigated or developed (Goldstein *et al.*, 2012).

Garnets (YAG)

Yttrium aluminum garnet (YAG, $\text{Y}_3\text{Al}_5\text{O}_{12}$) has excellent optical properties (transmission from 0.2 to 6 μm with up to 84% transmittance), good mechanical properties, reasonable thermal conductivity ($10.8 \text{ W} \cdot \text{m}^{-1}\text{K}^{-1}$), high thermal resistance ($T_M \sim 1950^\circ\text{C}$) and a cubic crystal structure that easily accommodates rare-earths dopants, enabling use as a laser host (Sanghera *et al.*, 2012). In addition, it is cheaper and/or optical quality material is easier to make than comparable materials, making it the most widely-used solid-state laser medium (Goldstein and Krell, 2016; Lupei, 2016). The most common dopants are Nd^{3+} (first demonstrated in 1964) and Er^{3+} for lasers, and Ce^{3+} for phosphors and scintillators, but a variety of other dopants (Yb^{3+} , Ho^{3+} , Cr^{2-4+} , Tm^{3+}) are used (Kong *et al.*, 2015; Lupei, 2016; Xiao *et al.*, 2019). It typically emits at 1064 nm, but can be frequency doubled (tripled, etc.) to emit in the visible. However, it has higher thermal expansion and lower thermal conductivity than sesquioxides (Sanghera *et al.*, 2012). Although typically made as single crystals, YAG is increasingly made polycrystalline. The intermediate compounds $\text{Y}_4\text{Al}_2\text{O}_9$ (monoclinic YAM) and YAlO_3 (perovskite YAP) in the Y_2O_3 - Al_2O_3 phase system at higher yttria contents require stoichiometry control during processing (Kong *et al.*, 2015). The reasonably-low vapor pressure up to 1850°C enables vacuum sintering of polycrystalline YAG at high temperature, but it has also been made by HP, SPS, and solid-state reaction and sintering, sometimes with added HIP, and additives like SiO_2 , MgO and CaO have been used to promote densification (Sanghera *et al.*, 2012; Kong *et al.*, 2015; Goldstein and Krell, 2016). Rods $> 20 \text{ cm}$ long and slabs $> 10 \times 10 \times 2 \text{ cm}$ have been fabricated and laser power outputs of over 100 kW achieved (Sanghera *et al.*, 2012). YAG has been used as laser hosts, phosphors and scintillators; in Q-switches and LED's, and as gemstones, but it also has potential as windows (Goldstein and Krell, 2016; Gemological Institute of America, 1995).

Other transparent garnets, such as $\text{Lu}_3\text{Al}_5\text{O}_{12}$ (LuAG), $(\text{Y,Gd})(\text{Ga,Sc})_3\text{Al}_5\text{O}_{12}$, $\text{Dy}_3\text{Al}_5\text{O}_{12}$ (DyAG), $\text{Tb}_3\text{Al}_5\text{O}_{12}$ (TbAG) and $\text{Tm}_3\text{Al}_5\text{O}_{12}$ (TmAG) have also been reported. These generally feature good thermo-mechanical properties with some being used or showing promise as laser hosts, scintillators, transparent luminescent ceramics for LED's and for magneto-optic applications (Sanghera *et al.*, 2012; Xie *et al.*, 2013b; Kong *et al.*, 2015; Li *et al.*, 2019). TbAG in particular has a high Verdet constant ($137 \text{ rad} \cdot \text{T}^{-1}\text{m}^{-1}$), which is useful for optical Faraday isolators in lasers to prevent back-reflected light from returning to the cavity (Li *et al.*, 2019).

Pyrochlores

Pyrochlore oxide ceramics with the general formula $\text{A}_2\text{B}_2\text{O}_{6/7}$, where cations are typically rare-earth or transition-metals, have a cubic structure and can exhibit good Vis-NIR transmittance, luminescence, excellent thermal resistance; insulating, ionic or metallic conduction; and piezo- and ferro-electric behavior (similar to perovskites) (Subramanian *et al.*, 1983). Several transparent pyrochlore ceramics with general type $(\text{La,Lu,Y,Gd,Nd})_2(\text{Zr,Hf})_2\text{O}_7$ (i.e., $\text{La}_2\text{Hf}_2\text{O}_7$) and $(\text{Y,Lu})_2\text{Ti}_2\text{O}_7$ (i.e., $\text{Y}_2\text{Ti}_2\text{O}_7$) have been reported, some featuring high transmittance (Wang *et al.*, 2018; Xiao *et al.*, 2019). Although they have potential for use as high-index lenses, lasers, transparent armor and scintillators, they are still being developed (Wang *et al.*, 2018).

Ferroelectrics

Perovskites (PLZT, PMN, PZN)

The cubic ABX_3 perovskite structure, where A and B are metal cations and X is typically oxygen, is adopted by a wide-range of compounds. In addition to transparency, perovskites can exhibit interesting properties such as electronic and ionic conduction, superconductivity, lasing, scintillating, ferroelectricity and magnetoresistance (Vasylechko *et al.*, 2009). Among these, ferroelectric behavior, which occurs below the Curie temperature (T_C) where a transition to paraelectric occurs, and which also consequently implies pyro- and piezo-electric behavior, can give rise to useful electrooptic effects (Haertling, 1999; Goldstein *et al.*, 2020).

Common ferroelectric ceramics include lead-lanthanum zirconate-titanate (PLZT, $\text{Pb}_{1-x}\text{La}_x(\text{Zr}_y\text{Ti}_{1-y})_{1-x/4}\text{O}_3$), lead-magnesium niobate - lead titanate (PMN-PT, $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})_3\text{-PbTiO}_3$) and lead-zirconium niobate - lead titanate (PZN-PT, $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3$), with many other elemental partial-substitutions possible. These combine pseudo-cubic perovskite (or distorted, pyrochlore or tetrahedral structures depending on doping, poling and temperature) with relaxor-ferroelectric, photorefractive and photochromic behavior, enabling unique applications (Haertling, 1999). Although visible transparency is low ($< 70\%$) due to high refractive indices, electrooptic coefficients are high (Xiao *et al.*, 2019). The most widely-used and mature is PLZT, with lanthanum substitution exceptionally beneficial for transparency (Goldstein *et al.*, 2020). Depending on composition, $T_C \sim 75\text{--}250^\circ\text{C}$ and electrooptic coefficients ($r_c 1.2\text{--}5.2 \times 10^{-10} \text{ m} \cdot \text{V}^{-1}$, $R 3.8\text{--}9.1 \times 10^{-16} \text{ m}^2\text{V}^{-2}$) are five times or more those of LiNbO_3 (a common ferroelectric with $r_c 0.17 \times 10^{-10} \text{ m} \cdot \text{V}^{-1}$) (Haertling, 1999; Uchino, 2000; Goldstein and Krell, 2016; Xiao *et al.*, 2019). However, PLZT exhibits high induction fields, polarization-dependent scattering and relatively large hysteresis (Kamzina *et al.*, 2010). PMT requires solid-solution with PT to increase T_C above ambient and has electrooptic coefficients ($r_c 24 \times 10^{-10} \text{ m} \cdot \text{V}^{-1}$, $R 66 \times 10^{-16} \text{ m}^2\text{V}^{-2}$) over 100 times greater than LiNbO_3 and a strong photorefractive effect (Haertling, 1999; Goldstein and Krell, 2016; Xiao *et al.*, 2019).

Goldstein *et al.*, 2020). PZN also features excellent ferroelectric properties and requires solid-solution with PMN or PT (Xiao *et al.*, 2019). Many other compositions have been fabricated, but lead toxicity and volatility during processing have motivated the development of lead-free transparent ferroelectrics. For example, $(\text{Sr},\text{Ba}_{1-x})\text{Nb}_2\text{O}_6$ (SBN), $\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$ (KTN), KH_2PO_4 (KDP), $\text{KSr}_2\text{Nb}_5\text{O}_{15}$ (KSN), $(\text{K},\text{Na})\text{NbO}_3$ (KNN), $(\text{K},\text{Na})\text{Nb}_{1-x}\text{Bi}_x\text{O}_3$ and BaZrO_3 - BaTiO_3 (BZT), with some of these featuring additional functional properties such as luminescence and photochromism (Dupuy *et al.*, 2016; Cao *et al.*, 2019; Xiao *et al.*, 2019; Goldstein *et al.*, 2020). Transparent ferroelectrics have been made using solid-state reaction, pressure-sintering, HP, SPS, and microwave sintering and are often made as thin-films using deposition methods (Xiao *et al.*, 2019). Applications include optical modulators and shutters, flash goggles, color filters, polarization controllers, segmented displays, image storage, energy storage, viewing systems, and night-vision systems (Levinson, 1987; Haertling, 1999; Kong *et al.*, 2015; Goldstein and Krell, 2016; Chai *et al.*, 2017). Non-ferroelectric perovskites can also have desirable properties, with $\text{Ba}(\text{Zr},\text{Mg},\text{Ta})\text{O}_3$ with $n = 2.08$ – 2.2 and Abbe number 40 commercialized as a high-index lens for electronics, and other compositions like SrHfO_3 investigated for laser media and thin-film epitaxy substrates (Krell *et al.*, 2009b; Goldstein and Krell, 2016).

Conducting oxides (ITO)

Transparent conducting oxides (TCOs) have the unique combination of transparency and electronic conductivity and are key enablers of technologies like pressure-sensitive displays. TCOs are dominated by combinations of indium (In_2O_3), zinc (ZnO) and tin oxide (SnO_2), and to a lesser extent gallium (Ga_2O_3) and cadmium oxide (CdO), with indium-tin oxide (ITO) prevalent (Pasquarelli *et al.*, 2011). TCOs generally have relatively high melting points but also high density, low hardness and high refractive indices. However, they transmit in the visible and can feature luminescence, high electron mobilities and semiconductor and piezoelectric behavior (Weber, 2003). TCOs are produced polycrystalline or amorphous and are often doped (i.e., Cl, F, Sb, Ti, Mo) (Pasquarelli *et al.*, 2011). Visible transparency can be up to 90% (thin coatings) with transmission windows spanning from 0.35 to 3.5 μm and resistivities from 1 to $8 \times 10^{-4} \Omega \cdot \text{cm}$ for ITO (Bright, 2013). Moreover, they can absorb UV and reflect IR wavelengths, making them useful heat reflectors with UV protection. TCO's are applied as thin-films and have been made by spray-pyrolysis, sputtering, CVD, PVD, PLD, ALD and chemical solution deposition (Pasquarelli *et al.*, 2011). Applications include flat-panel/LCD displays, TV monitors; touch-sensitive displays, electrochromic windows and LED's (as transparent electrodes); photovoltaics (as transparent current collectors), conductive antireflection coatings, transparent heating conductors for aircraft windshields, transparent thin-film transistors (TFT's) for flexible electronics, electromagnetic interference shielding, laser diodes and antistatic films (Pasquarelli *et al.*, 2011; Lewis and Paine, 2000). The individual oxides used in TCOs also have interesting properties and are used in niche applications. For example, ZnO features good transparency, low thermal expansion, high thermal resistance (T_D 1974°C), high electron mobility ($2000 \text{ cm}^2 \cdot \text{V}^{-1} \cdot \text{s}^{-1}$ at 80K), and luminescent, semiconducting and piezoelectric behavior, finding (potential) use in UV laser diodes, heat-protection and transparent conducting coatings (Borysiewicz, 2019).

Complex-anion (silicates, apatites) and other oxides

Transparent complex-anion ceramics have been reported but they are not yet used commercially. Mullite is a solid-solution with general formula $\text{Al}_6\text{Si}_2\text{O}_{13}$ and orthorhombic structure. It is a widely-used opaque engineering material due to low density ($\sim 3.2 \text{ g} \cdot \text{cm}^{-3}$) and reasonable strength (200 MPa), fracture toughness ($K_{IC} \sim 2.5$) and hardness (10 GPa), combined with superior high-temperature stability ($T_M \sim 1830^\circ\text{C}$), high thermal-shock resistance, and low thermal expansion ($\sim 4.5 \times 10^{-6} \text{ K}^{-1}$), thermal conductivity ($\sim 7 \text{ W} \cdot \text{m}^{-1} \text{ K}^{-1}$) and dielectric constant. It has been prepared by HP, HP-HIP, pressureless sinter-HIP, microwave sintering, vacuum sintering and SPS. Although visible transmittance is low, up to 88% transmittance has been achieved in the IR (Ren *et al.*, 2015; Xiao *et al.*, 2019). Translucent/transparent rare-earth doped Lu_2SiO_3 and oxy- and fluoro-apatite ($\text{Sr}_2\text{Y}_8(\text{SiO}_4)_6\text{O}_2$, $\text{Sr}(\text{PO}_4)_3\text{F}$ and $\text{Ca}_5(\text{PO}_4)_3\text{F}$) ceramics with promising laser and scintillator properties and transparent hydroxyapatites for biomedical applications have also been reported (Uematsu *et al.*, 1989; Shen *et al.*, 2012; Chen *et al.*, 2013; Kim *et al.*, 2017; Furuse *et al.*, 2019). Transparent strontium aluminosilicate ($\text{Sr}_{1+x/2}\text{Al}_2+x\text{Si}_{2-x}\text{O}_8$) ceramics with high transmission (90%, 1.5 mm thick), tellurite ceramics (TeO_2 - Nb_2O_5 - Bi_2O_3) and ion-conducting transparent ceramics ($\text{Ln}_{1+x}\text{Sr}_{1-x}\text{Ga}_3\text{O}_7$) have been fabricated by full crystallization from glass (Saghir, 2014; Boyer *et al.*, 2018), as have other simpler structures (BaAl_4O_7 , $\text{Sr}_3\text{Al}_2\text{O}_6$), with potential applications ranging from lenses to laser hosts (Bertrand *et al.*, 2016). Many other transparent oxides are being investigated, developed or used in niche applications. Examples range from high-hardness coesite SiO_2 , to optoelectronic TiO_2 , conductive vanadium oxides, and refractories like HfO_2 , CeO_2 and ThO_2 (T_M 3350°C) to name a few (Anderson, 1972; Chain, 1991; Weber, 2003; Xie and Hintzen, 2013a; Mazzolini *et al.*, 2015; Kulik *et al.*, 2018).

Oxynitrides

Oxygen and nitrogen share similar chemical and electronic characteristics that enable their substitution in oxides and nitrides, forming the large oxynitride group. These feature substantial structural diversity and unique properties that can be tailored by varying the O/N ratio. ALON is the only bulk material used commercially, while other compositions (MgAlON , LiAlON , TiO_xN_y) are being investigated, developed or used as coatings (Xiao *et al.*, 2019). Oxynitrides have similar potential applications as oxides and nitrides, such as transparent armor, scratch-resistant windows, optical elements, and thin-film antireflection, heat-mirror and solar absorber coatings (Xie and Hintzen, 2013a).

AlON

It was discovered in the 1970s that substituting ~ 5 wt% nitrogen for oxygen in Al_2O_3 stabilizes the cubic γ - Al_2O_3 phase, enabling the possibility of highly-transparent thick-sections with similar mechanical properties as Al_2O_3 (McCauley and Corbin, 1980; McCauley *et al.*, 2009). The material was trademarked as ALONTM with composition $\sim 9\text{Al}_2\text{O}_3\text{-}5\text{AlN}$ ($\text{Al}_{23}\text{O}_{27}\text{N}_5$). The Al_2O_3 -AlN phase diagram is complex, with the cubic solid-solution phase existing within a range centered at 35.7 mol% AlN (McCauley *et al.*, 2009). ALON has similar physical properties as Al_2O_3 , with high transmission from the UV to the MWIR but with a slightly lower IR cut-off (Harris, 1999). Commercial ALON has relatively large grain size (150–200 μm) and hardness HV ~ 15 –16 GPa. Although hardness is lower than Al_2O_3 , it is higher than competing materials and there is ample opportunity for further improvement through grain-size refinement. ALON fabrication is complicated by high-temperature vapor phases and requires precise temperature and atmosphere control. It was first produced by reaction sintering cold-pressed Al_2O_3 and AlN reactants in N_2 at high temperature (Savage, 1991). It has since been made using green-body formation methods like slip-casting and injection molding, and densified by pressureless sintering, transient liquid-phase sintering, HP, HIP, microwave sintering, and SPS in N_2 atmosphere, often starting with ALON powders, which are themselves difficult to synthesize (Savage, 1991; Patel *et al.*, 2000; McCauley *et al.*, 2009; Kong *et al.*, 2015; Kumar and Johnson, 2016). Sizes up to 45×90 cm or larger by edge-bonding have been made (Surmet Co., 2020). Although it has excellent properties and the technology is well-developed, ALON is more expensive than competing ceramics like spinel (Patel *et al.*, 2000). Applications are similar to sapphire and spinel, including missile domes, military lenses and windows, transparent armor, laser and scanner windows, high-energy discharge and sodium-vapor lamp envelopes and semiconductor applications (Silva and Boccacini, 2008; McCauley *et al.*, 2009). Other oxynitrides find use as hard, scratch-resistant and/or antireflective coatings (Xie and Hintzen, 2013a).

Chalcogenides

Non-oxide chalcogenides (sulfides, selenides, and tellurides) are characterized by high melting points, chemical stability, moderate thermo-mechanical properties and IR transmittance. Zinc sulfide and selenide are common IR materials, while others are used in niche applications, such as CdS thin-coatings for photovoltaics and single-crystal PbF_2 for IR detectors (Harris, 1999).

Sulfides/Selenides (ZnS, ZnSe)

Zinc sulfide (ZnS) and selenide (ZnSe) are wide-bandgap semiconductors with a long history as the most important IR optical materials. Both are cubic, but ZnS transforms to a hexagonal phase $> 1020^\circ\text{C}$ (McCloy, 2007). ZnS has a high refractive index (n 2.36 at 600 nm), a wide transmission window (0.4–12.5 μm), sometimes high visible and usually excellent IR transmittance, especially in the LWIR (8–10 μm). It has relatively poor mechanical properties and high density ($4.09 \text{ g} \cdot \text{cm}^{-3}$), but moderate thermal-shock resistance and increasing strength with temperature. ZnS oxidizes $> 800^\circ\text{C}$ and sublimates $> 1200^\circ\text{C}$, while ZnSe sublimates $> 400^\circ\text{C}$ (Goldstein *et al.*, 2020). ZnSe has better optical quality, with excellent MWIR (3–5 μm) and LWIR transmittance, but lower mechanical properties and poor thermal-shock resistance. Attempts have been made to improve this by alloying with diamond, GaP or other materials, and by laminating with ZnS. Although ZnSe is an excellent material for laser windows, it is not durable enough for external use. Both materials are relatively soft, have low erosion resistance and usually require coatings for demanding applications (Harris, 1999). ZnS and ZnSe are primarily made by chemical vapor deposition (CVD) and HIP, and previously by HP. CVD ZnS typically has an amber color and is composed of cubic and hexagonal phases and can contain absorbing hydride impurities. Post-HIP restores stoichiometry, removes hydrogen, and converts hexagonal grains to cubic, albeit at the expense of grain growth (Harris, 1999). ZnS and/or ZnSe are used or proposed as IR windows and domes, phosphors and anti-reflective thin-films, and in CO_2 laser optics, LED's, blue LED lasers, IR laser gain media and scintillators (Harris, 1999; McCloy, 2007).

Fluorides

The highly-ionic character of alkaline/alkaline-metal fluorides confers exceptionally-low refractive indices (1.33 at 633 nm for NaF) and dispersion along with wide transmission windows (including the MW), enabling transmittances surpassing SiO_2 over a broad range (Harris, 1999; Weber, 2003; Stevenson *et al.*, 2011). LiF and MgF_2 have the lowest UV absorption edges of known materials (~ 0.11 – 0.12 nm) (Tropf *et al.*, 1995). However, many fluorides are water-soluble (NaF) or hygroscopic (LiF, MgF_2) and uncoated LiF degrades in humidity (Elliot, 1995; Xiao *et al.*, 2019). Fluorides with heavier cations (CaF_2 , SrF_2 , BaF_2 , and PbF_2) transmit further in the IR while maintaining UV-vis transparency, enabling use in the MWIR and LWIR (Stevenson *et al.*, 2011). Fluorides also have desirable laser properties, including low or negative thermo-optic coefficients (dn/dT), which can partially compensate thermal lensing effects, high absorption/emission cross sections, and lower thermal expansion and non-radiative decay rates and weaker crystal fields than some oxides (Stevenson *et al.*, 2011). Although, thermal expansions are higher and thermal conductivities lower than garnets and sesquioxides (Sanghera *et al.*, 2012). The main laser-gain materials are CaF_2 , LiYF_4 , LiSrAlF_6 and LiCaAlF_6 , while CaF_2 , BaF_2 and CeF_3 have been investigated as scintillators for ionizing radiation (Stevenson *et al.*, 2011). Fluorides are also used as UV-Vis-IR optical components, coatings and windows and domes. Although fluorides are commonly used as single-crystals, MgF_2 and CaF_2 (more commonly), and SrF_2 are also made polycrystalline (Harris, 1998). Other transparent polycrystalline fluorides, including high-entropy compositions have also been reported (Chen and Wu, 2019). Although they can have low density and high melting points,

fluorides are relatively soft, often lack thermal-shock resistance, have high thermal expansions and are susceptible to solarization (Harris, 1999; Elliot, 1995; Sanghera *et al.*, 2012; Xiao *et al.*, 2019).

Magnesium fluoride

Magnesium fluoride (MgF_2) has a low refractive index (n 1.37), low dn/dT ($1.2/0.6 \times 10^{-6} \text{K}^{-1}$ at 633 nm), an exceptionally-low UV absorption edge ($\sim 0.12 \text{ nm}$), a wide transmission window (up to $7\text{--}9 \mu\text{m}$), low density ($3.15 \text{ g}\cdot\text{cm}^{-3}$) and moderate thermomechanical properties (Harris, 1999; Weber, 2003). However, the tetragonal structure is slightly birefringent and the strength and thermal-shock resistance are relatively low (Harris, 1999; Xiao *et al.*, 2019). It is nevertheless rugged enough to be used in missile domes and has resistance to laser damage (Harris, 1999; Kong *et al.*, 2015). Transparent material is typically HP but achieved transparency remains low (Xiao *et al.*, 2019). Applications include UV and UV-laser components, antireflection coatings and IR windows and domes (Elliot, 1995; Kong *et al.*, 2015; Goldstein and Krell, 2016).

Calcium fluoride

Calcium fluoride (CaF_2) has a cubic fluorite structure, a low refractive index (n 1.43) rendering high transmittance ($> 90\%$ in the IR) and a wide transmission window ($0.13\text{--}10\text{--}12 \mu\text{m}$), enabling use from the UV to the MWIR/LWIR. $\text{U}^{3+}:\text{CaF}_2$ was the second laser material and HP $\text{Dy}^{2+}:\text{CaF}_2$ was the first ceramic laser material (Sorokin and Stevenson, 1960; Hatch *et al.*, 1964; Stevenson *et al.*, 2011). Although it has low density ($3.18 \text{ g}\cdot\text{cm}^{-3}$) and good thermal conductivity ($9.7 \text{ W}\cdot\text{m}^{-1}\text{K}^{-1}$), it is relatively fragile, with weaker thermomechanical properties and higher thermal expansion than MgF_2 and it colors under UV irradiation (Elliot, 1995; Stevenson *et al.*, 2011). Transparent material has been made by HP, sinter-HIP and SPS with various dopants (Yb^{3+} , Er^{3+} , Ho^{3+}) for laser applications (Xiao *et al.*, 2019). CaF_2 is used in UV and IR lasers, with $\text{Yb}:\text{CaF}_2$ of interest for high-power lasers; windows and lenses for thermal imaging, spectroscopy and telescopes; scintillators, thermoluminescent dosimeters and previously as high-performance single-crystals in optical devices due to its low dispersion (Elliot, 1995; Stevenson *et al.*, 2011; Goldstein and Krell, 2016).

Chlorides, Bromides and Iodides

Halogens such as chlorides, bromides and iodides generally have poor thermomechanical properties and are often water-soluble, but they can feature low refractive indices and dispersion (chlorides) and wide transmission windows with excellent transmittance up to the far IR (bromides and iodides). They are generally used as single-crystal IR materials (NaCl , KCl , KBr , KI , CsI , AgBr , AgI , etc.), but some materials, like KCl and SrI_2 (a widely-used commercial scintillator material) have also been made polycrystalline, for example by hot forging (KCl) (Harris, 1999; Cherepy *et al.*, 2011).

Nanocomposites

Nanocomposites aim to take advantage of synergetic effects of constituents to potentially yield improved properties. However, depending on the refractive index difference, the grain size must be less than $20\text{--}30$ times smaller than transmitted wavelengths to maintain reasonable transmittance (Harris *et al.*, 2013). Fortunately, this can be assisted by grain-growth inhibition due to constituent immiscibility. Several transparent composites have been reported, including $\text{ZrO}_2\text{--ThO}_2$, $\text{MgO--Y}_2\text{O}_3$, $\text{ZrO}_2\text{--MgO--Y}_2\text{O}_3$, $\text{MgAl}_2\text{O}_4\text{--Si}_3\text{N}_4$ and $\text{MgAl}_2\text{O}_4\text{--YAG}$ (Gledhill *et al.*, 2012; Wang *et al.*, 2012; Kong *et al.*, 2015). $\text{MgO--Y}_2\text{O}_3$ was developed as an IR-transmitting ceramic and generally has physical properties intermediate between the constituents, but it exhibits twice the strength and thermal shock resistance (Harris *et al.*, 2013).

Coating Materials

Thin- and thick-films, and to a lesser extent, claddings, represent one of the most important applications for transparent ceramics in terms of diversity, comprising the entire gamut of materials. Coating materials are too numerous to iterate here, but examples include diamond, SiC , GeC , AlN , TiN , Si_3N_4 , MgO , ITO , ZnO , SnO_2 , TiO_2 , ZrO_2 , HfO_2 , ThO_2 , HfO_2 , CeO_2 , Al_2O_3 , Y_2O_3 , Sc_2O_3 , Cr_2O_3 , Ta_2O_5 , Nb_2O_5 , TiON , ZnS , As_2S_3 , ZnSe , GaP , BP , LiF , MgF_2 , AlF_3 , PbF_2 , LaF_3 , HfF_4 , YF_4 , ZrF_4 , ThF_4 , and CeF_3 (Dobrowolski, 1995; Xie and Hintzen, 2013a; Lee and Kuo, 2013). Coatings are used in applications ranging from flat-panel displays, LED's, sunglasses, automotive and aircraft windows, Vis-IR windows and domes, laser windows and UV-protective and heat-mirror windows.

Summary

Considering their remarkable and varied properties, if the last half-century is any guide, transparent ceramics will likely not only experience strong growth in their current niches, but also find use in many new applications. Hundreds of new materials are in the pipeline or yet to be discovered, and these will undoubtedly add to the great variety of current materials. Advances in processing are enabling ever more complex structures and difficult to sinter materials to be produced. As technology improves and costs are

reduced, transparent ceramics are finding application where only polymers and glasses were used. Moreover, polycrystalline materials will surely continue to expand into applications where previously only single crystals were used. Furthermore, polycrystalline ceramics will continue to be optimized with fewer flaws and ever smaller grain sizes, resulting in improved physical properties. Manufacturing technology is also rapidly advancing to produce ever larger sizes and geometries while reducing cost. Finally, thin-films and thicker coatings, whether single or multi-layer, are especially promising to enable new applications in fields as varied as mobility, energy and health care.

Geopolymers and Geopolymer-Derived Composites

Waltraud M Kriven, University of Illinois at Urbana-Champaign, Urbana, IL, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

Geopolymers are polysilicate-aluminate, inorganic polymers or chemically bonded ceramics made under highly alkaline (NaOH, KOH, CsOH) or highly acidic (H_3PO_4) conditions. (Davidovits, 1982, 1988, 1991, 2020; Barbosa *et al.*, 2000; Barbosa and MacKenzie, 2003; Duxson *et al.*, 2005; Kriven *et al.*, 2003; Kriven, 2010, 2018; Kriven *et al.*, 2007a,b). The alkali-based geopolymers have been reasonably well studied over the past twenty years, while the acid-derived polymers are the subject of more recent study. The alkali-based composition is centered around the stoichiometric composition $\text{M}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 11\text{H}_2\text{O}$ where M is a Group I alkaline element in the Periodic Table. The number of water molecules varies depending on the desired viscosity and the particle size and specific surface area of the starting aluminosilicate powder. Acid-based geopolymers are centered around the composition $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ and do not contain free charge-balancing cations. These are sometimes referred to as di silico-alumino-phosphates, silico-alumino-phosphates or “SAPs” and their atomic structure consists of covalently bonded SiO_4 , AlO_4^- and PO_4 tetrahedra.

Geopolymers can be thought of as a refractory “glue” which binds various filler phases or reinforcements together to form structural composites that can be scaled up to large sizes without the need for firing. Since the geopolymer reaction takes place during high shear and under ambient conditions in aqueous solution or as a paste containing filler phases, the reinforcements can be traditional particulates, chopped fibers, unidirectional or woven fibers of ceramics as well as of polymers, metals or biological reinforcements. The fabrication of geopolymer composites can be readily scaled up or additively manufactured into large bodies due to their ambient setting conditions.

The properties of alkali activated geopolymer (GP) from metakaolin have been compared with those of Ordinary Portland Cement (OPC) by Davidovits (2020) and Kriven (2018). The synthesis of GP releases only 25% of the carbon dioxide that the synthesis of OPC which releases ~ 0.95 tons of CO_2 per ton of cement manufactured. However, the intrinsic compressive strength of geopolymer composites (GPC) is almost double that of OPC (100–120 MPa) as compared to ~ 60 MPa for OPC composites. The flexural strength of GPCs are at least 2–5 times stronger than that of OPC composites, while the density of geopolymers is of the order of 1.5 g/cc which is half that of OPC. A significant advantage of GPC is that their setting time to achieve full strength is 1–3 days as compared to 28 days for OPC.

Since geopolymers consist of nanoparticulate and nano-porous bodies under ambient temperatures, the self-assembled nanoparticles result in nano diffusion path lengths, which open the way to the synthesis of ultra-high temperature ceramics, via lower energy pathways than are currently being used. While geopolymer composites are made under ambient conditions, alkali activated, metakaolin-based geopolymers are able to withstand high temperatures up to $\sim 1000^\circ\text{C}$, whereupon they crystallize and convert into a polycrystalline ceramic. Depending on the charge-balancing cation composition the resulting crystallized ceramic exhibits a range of tailorable thermal expansion coefficients, opening up the possibilities for their application as thermal barrier coatings on metals or on other ceramics to which they may adhere. As a refractory glue of tailorable thermal expansions, alkali-based geopolymers can act as adhesives and join ceramic and metals with minimal stresses upon heating.

The loss in mechanical properties resulting from dehydration and microcracking at ~ 250 – 400°C , as well as crystallization at $\sim 1000^\circ\text{C}$, can be counterbalanced by “self-healing” of the composite with the inclusion of a glass frit which melts and flows into the matrix, restoring some of the mechanical properties up to the melting temperature of the glass. This leads to the introduction of amorphous self-healed geopolymer (ASH-G) or amorphous self-healed ceramics (ASH-C). Thus, geopolymers are a new generation of inorganic polymers that are made under ambient temperatures, like a polymer or cement, but can have the eventual high temperature properties of a ceramic.

Metakaolin-Based, Alkali-Activated Geopolymers

The alkali-based geopolymers have a solid solution range which can be approximated by the formula $\text{M}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 11\text{H}_2\text{O}$ where M is a group I element, such as Na, K, Cs. Traditionally this composition has been chosen, because for K or Cs, high temperature heat treatment to $\sim 1000^\circ\text{C}$ would lead to crystallization into a single phase, stoichiometric compound, rather than into a mixture of ceramic plus glass, which occurs when the formulation deviates from this stoichiometry, according to their corresponding phase diagrams. In the case of $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 11\text{H}_2\text{O}$ leucite starts to crystallize at 950°C and melts at 1693°C (Bell *et al.*, 2008b, 2009b). The composition $\text{Cs}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$ crystallizes at 1050°C into pollucite which melts at 1940°C (Bell *et al.*, 2008a, 2009a). In the case of sodium, the geopolymer crystallizes into glass plus nepheline ($\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) which melts at 700°C (after forming at 1000°C). The $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$ analog does not form under ambient pressures but it requires a geological pressure of 1.7 GPa and 1250°C to form jadeite, the toughest mineral known. The amount of water is variable, depending on the particle size and specific surface area of the aluminosilicate starting material, as well as the desired viscosity and workability of the paste. It is released during heating at ~ 250 – 400°C .

Fig. 1 Dissolution of the aluminosilicate source (e.g., metakaolin, $\text{Al}_2\text{O}_3 \bullet 2\text{SiO}_2 \bullet 2\text{H}_2\text{O}$) is due to dehydration of crystalline kaolinite (a) where the Al^{3+} is in 6-fold octahedral coordination, to decompose into amorphous metakaolin (b) where a highly strained 5-fold coordinated Al^{3+} polyhedron forms a double bond with oxygen. Upon dissolution in waterglass, a regular AlO_4^- tetrahedron (c) springs into existence and is ready to polymerize in 3D with silicate tetrahedra.

Alkali-based geopolymers are refractory, inorganic polymers formed from both aluminum and silicon sources containing AlO_4^- and SiO_4 tetrahedral units and set under highly alkaline conditions (e.g., NaOH, KOH, CsOH) at ambient temperatures (Davidovits, 1982, 1988, 1991, 2020; Barbosa *et al.*, 2000; Barbosa and MacKenzie, 2003; Kriven *et al.*, 2003, 2005, 2007a,b; Kriven, 2010; 2018; Duxson *et al.*, 2005, 2007; Sa Ribeiro *et al.*, 2017). In materials science, geopolymers are made from kaolinite clay of composition $\text{Al}_2\text{O}_3 \bullet 2\text{SiO}_2 \bullet 2\text{H}_2\text{O}$ which is heated at $\sim 750^\circ\text{C}$ for 2 h and converted to amorphous metakaolin ($\text{Al}_2\text{O}_3 \bullet 2\text{SiO}_2$). Geopolymers can also be formed from other aluminosilicate clays such as bentonite, laterite or halloysite, the latter being basically nanotubular kaolinite (Barbosa *et al.*, 2000; Barbosa and MacKenzie, 2003). When mixed under high shear with the waterglass solution (e.g., of composition $\text{M}_2\text{O} \bullet 2\text{SiO}_2 \bullet 11\text{H}_2\text{O}$), it undergoes dissolution, polycondensation and precipitation reactions under ambient conditions to form a geopolymer solid, where all the silicate and aluminate tetrahedra are corner-shared.

Geopolymers are a rigid, hydrated, alumino-silicate solid or gel containing group I, charge-balancing cations. The reason that these ceramic-like, aluminosilicates form under ambient temperatures is attributed to the highly strained state of the pentavalent AlO_5 molecule in the amorphous metakaolin, as illustrated in Fig. 1 (Kriven (2018)). The $\text{Al}=\text{O}$ double bond is susceptible to attack by the highly concentrated alkali solution which constitutes the rate determining step. Upon dissolution of the aluminosilicate source, tetrahedra of AlO_4^- and SiO_2 form in solution and polymerize to form the 3D bonded aluminosilicate, where the AlO_4^- is charge balanced by nearby Group I cations of Na^+ , K^+ , or Cs^+ surrounded by waters of solvation.

The currently accepted molecular structure of geopolymers is represented in Fig. 2, taken from Barbosa *et al.* (2000), Barbosa and MacKenzie (2003). In magic angle spinning, nuclear magnetic resonance (MAS NMR) it is seen that the silicate and aluminate (AlO_4^-) tetrahedra share all four of their corners with each other, forming $\text{Si}-\text{O}-\text{Si}$ or $\text{Si}-\text{O}-\text{Al}$ bonds, corresponding to the Q^4 notation used in NMR (MacKenzie and Smith, 2002). They form in an amorphous, cross-linked, impervious, acid-resistant, 3-D structure and their microstructure, as seen by high resolution TEM in Fig. 3, is nanoparticulate ($\sim 20\text{--}40\text{ nm}$) and nanoporous ($\sim 6.8\text{ nm}$ diameter) (Kriven, 2018). The intrinsic mechanical properties of metakaolin-based, alkali activated geopolymers have been measured and summarized (Cho, 2015; Kriven, 2018) and theoretically predicted (Akono *et al.*, 2019).

The intrinsic mechanical properties of geopolymers derived from BASF Metamax® metakaolin were systematically studied by several workers, as reviewed by Kriven (2018) and analyzed in terms of Weibull statistics (Weibull, 1951). The intrinsic mechanical properties of single-phase, potassium-based geopolymers (KGP) made from BASF metakaolin are summarized in Table 1. Some of these properties have also been predicted by Akono *et al.* (2019).

Metakaolin-Based, Acid-Activated Geopolymers

Metakaolin can be reacted with concentrated phosphoric acid (H_3PO_4) and converted into an alumino disilicate phosphate geopolymer. Chemically, the inorganic polymer consists of tetrahedra of silica, alumina and phosphate (PO_4), without the need for charge balancing cations. A confirmed composition is $\text{Al}_2\text{O}_3 \bullet 2\text{SiO}_2 \bullet \text{PO}_4$ in a 1:2:1 molar or 1:1:1 atomic cation ratio, and is also called a "SAP". These inorganic polymers having been gaining interest in the past few years, (Perera *et al.*, 2008; Wagh, 2004; Prabakar *et al.*, 1991; Liu *et al.*, 2010; Cui *et al.*, 2011; Colorado *et al.*, 2011; Gualtieri *et al.*, 2015; He *et al.*, 2016; Douiri *et al.*, 2016; Tchakouté *et al.*, 2017; Wang *et al.*, 2017, 2019; Celerier *et al.*, 2018; Katsiki *et al.*, 2019; Mathivet *et al.*, 2019; Zribi *et al.*, 2019; Davidovits, 2020).

The aluminosilicate phosphate polymers are thought to have superior thermal stability, ionic conductivity, as well as higher compressive and flexural strengths compared to alkali activated, metakaolin-based geopolymers. Enhanced dielectric properties have been reported for this class of inorganic polymers (He *et al.*, 2016; Douiri *et al.*, 2016; Cui *et al.*, 2011). The aluminosilicate phosphates can be prepared from metakaolin, but have also been prepared from a sol-gel derived aluminosilicate. In this method, tetraethylorthosilicate (TEOS) is mixed with aluminum nitrate nonahydrate in ethanol, followed by drying at 100°C for

24 h, and then calcining at 800°C for 2 h. Ball milled particles of this aluminosilicate of composition $Al_2O_3 \cdot 2SiO_2$ are reacted with 10 molar phosphoric acid (H_3PO_4) at RT and after ~ 1 day an aluminosilicate network is formed. When this sol gel derived polymer is heated slowly from 40 to 200°C however, phase separation occurs to form SiO_2 and aluminum phosphate ($AlPO_4$) (Morris *et al.*, 1977). The nature and stability of these product phases is not well understood at present.

Ground particles of SAPs that have been cured at room temperature for 6 months tended to be amorphous and featureless in the TEM (Fig. 4). This is unlike the TEM microstructure of alkali activated, metakaolin-based geopolymers seen in Fig. 3. When a SAP was cured at 50°C for 24 h followed by heat treatment at 140°C for a further 24 h, its microstructure as seen by SEM was nanoporous (Fig. 5) and contained submicron precipitates, presumably of submicron aluminum phosphate ($AlPO_4$) and phase separated silica (SiO_2) (Fig. 6). Further, more detailed studies are in progress.

Metakaolin-Based Geopolymers Versus Alkali Activated Cements From Slag and Fly Ash Waste Materials

The term “geopolymer” has different meanings to different scientific communities. In the civil engineering community, the term “geopolymers” refers to the product resulting from high shear mixing of class F fly ash and ground granulated blast furnace slag

Table 1 Intrinsic mechanical properties of pure potassium-based geopolymer

Mechanical property (MPa)	Weibull parameters				
	Scale value (σ_0 , MPa)	# of samples	Shape (m)	Standard deviation (MPa)	95% CI (MPa)
Uniaxial compressive strength ^a	107.0	12	9.0	13.4	100.3–114.3

**Fig. 4** TEM micrograph of aluminosilicate phosphate (SAP) made from a sol gel aluminosilicate precursor ($\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) cured at room temperature for 6 months (a), showing featureless, amorphous microstructure as seen by its amorphous diffraction pattern in the corresponding SAD pattern (b).

waste products. They are prepared under high shear mixing in the same way as are metakaolin-based, alkali-activated geopolymers. The solid is also amorphous or crystalline but it is based on the calcium silicate hydrate (CSH), calcium aluminosilicate hydrate i.e., C(A)SH, potassium aluminosilicate hydrate (KASH), and sodium aluminosilicate hydrate (i.e., NASH) (i.e., charge balanced with Na^+ or K^+ ions) binder phases, all of which are the binder phases in cements. They are made up of Q^2 and some Q^3 tetrahedral units and contain only minor amounts of Q^4 bonded tetrahedral units, if any. In the cements structure, the silicate or aluminate tetrahedra form layers sharing only two or sometimes three corners, and are separated by layers of $\text{Ca}(\text{OH})_2$ or CaO . CSH is the main binder phase in Portland cement (Sankar et al., 2017, 2019a,b). One main difference between the cements versus metakaolin-based geopolymers is that the metakaolin-based geopolymers are chemically stable up to $\sim 1000^\circ\text{C}$, after which they

Fig. 5 SEM micrograph of alumino disilicate phosphate (SAP) (cured at 50°C/24 h followed by heat treatment at 140°C/24 h). Nanoporosity is evident.

Fig. 6 SEM micrograph of submicron precipitates of alumino disilicate phosphate (SAP) that had been cured at 50°C/24 h followed by heat treatment at 140°C/24 h. Submicron precipitates assumed to be aluminum phosphate (AlPO_4) in a silicate matrix were observed.

crystallize into a polycrystalline ceramic. When composites are formed with metakaolin-based geopolymers, some mechanical strength can be still be retained. Cements, on the other hand, contain significantly more water and so steadily decompose with increasing temperature, losing most of their mechanical strength by 700°C.

The difference between the molecular structures of alkali activated cements versus geopolymers is illustrated in [Fig. 7](#). Calcium silicate hydrates in cement contain significantly more water than do geopolymers. Thus metakaolin-based geopolymers are made like a cement, except under higher shear than in cements, but can behave like a ceramic. Cements will always remain as mainly low temperature capable materials ([Fig. 8](#)). While cements can be 3D printed, geopolymers exhibit thixotropic rheology and so can also be 4D printed, with time as the 4th parameter.

Geopolymer Composites

Numerous metakaolin-based, alkali-activated geopolymer composites have been made and reported as summarized by [Davidovits \(2020\)](#) and [Kriven \(2018\)](#). In general, their flexural strengths tend to be lower than those of conventional ceramics fired at high temperatures, but geopolymers usually exhibit higher toughness or graceful failure. Examples of flexural strengths of metakaolin-based, alkali activated, geopolymer composites are summarized in [Tables 2](#) and [3](#). Uniaxial carbon fiber reinforced geopolymer exhibited a dramatic increase in flexure strengths.

Porous Geopolymers

Geopolymers can be made porous by several means ([Bell and Kriven, 2004](#); [Kriven et al., 2004, 2007a,b](#); [Bell and Kriven, 2008](#); [Landi et al., 2013](#); [Glad and Kriven, 2014, 2015](#); [Medpelli et al., 2014](#); [Seo et al., 2013](#); [Sharma et al., 2015](#); [Ge et al., 2015](#); [Rincón Romero et al., 2018](#); [Tang et al., 2015](#); [Zhao et al., 2020](#); [Prud'homme et al., 2010, 2015](#); [Kamseu et al., 2012](#); [Akono et al., 2019](#)). Discrete pores of 45 μm in diameter can be made by addition of hydrogen peroxide ([Bell and Kriven, 2004](#); [Kriven et al., 2004, 2007a,b](#)). Another ecologically friendly way to make porous geopolymer is through the addition of vegetable canola oil to

geopolymer paste during synthesis causing phase separation to form an oil - aqueous phase emulsion (Medpelli *et al.*, 2014; Seo *et al.*, 2013; Sharma *et al.*, 2015). After the geopolymer has set, the oil is removed by boiling in water, leaving an interconnected porous network.

Geopolymer aerogels have been made containing 70 vol% porosity of just less than 1 mm pore size which have been developed through the Pickering emulsion effect (Glad and Kriven, 2014, 2015). Alkylalkoxysilanes were used to form a hydrophobic film on pore interiors during synthesis and drying, allowing for drainage without pore collapse. Pore volume and pore size could be tuned by manipulating initial water content, quantity of hydrophobic phase, drying humidity, and emulsion stability. Geopolymer reactivity was notably increased via premixing the geopolymer reagents in a dilute slurry prior to creating the emulsion. The geopolymers created were monolithic solids, which could be optionally calcined in inert atmosphere to form a porous ceramic glass with a crystalline β -SiC minor phase.

Conversely, mesoporosity (defined as pores of 2–50 nm diameter) in metakaolin Na-based GP can be reduced by an order of magnitude through the addition of acrylate-functional silane coupling agents (Glad and Kriven, 2014). Geopolymer densification and porosity reduction were achieved through the use of hydrogel chemistry. While traditional hydrogels are difficult to integrate into the GP matrix during the curing process, alkoxysilanes functionalized with methacrylate groups mixed into the GP slurry and formed micrometer-sized membranes and rolled tubes. It was found that a critical concentration of approximately 0.06 mol methacryloxypropyltrimethoxysilane/mol GP was necessary for extensive property modification.

The methacrylate/ mol GP was required for substantial surface area reduction, increased linear shrinkage and increased water retention characteristics, and that smaller amounts of the additive may even reverse the trends. It is suspected that the critical

Table 2 Summary of flexure strengths of geopolymer composites (GPCs) with various inorganic reinforcements

Reinforcement	wt% Additions	Flexure strength (MPa)
Chamotte (25 μm)	50	15.33
Dolomite (45 μm)	20	15.92
Mica phlogopite platelets (50–100 μm)	20	11.4
Granite powder ($\leq 90 \mu\text{m}$)	55	10.3
Dicalcium phosphate ($2\text{CaO} \cdot \text{P}_2\text{O}_5$)	15	10.4
Hydroxyapatite bone ash	15	10.0
Bangladeshi Mymensingh clay containing 40 wt.% quartz reinforced with dicalcium phosphate ($2\text{CaO} \cdot \text{P}_2\text{O}_5$) and glass frit	7.5	14.3

composition observed may occur at the concentration where the GP network is fully saturated with organic additive, so that only additional additive causes the observed porosity reduction. With 0.10 mol methacrylate/mol GP, the natural GP mesoporosity was reduced by approximately an order of magnitude, and the Weibull modulus was increased by almost 50% even for reinforced GP composites. Above this concentration, membranes and tubes of organic material could be observed, suggesting that only this surplus additive contributed to mesoporosity reduction. The source of this mesoporosity reduction was shown to be segregation of free water via hydrogel-like interaction caused by the formation of sodium acrylate groups.

Amorphous Self-Healed Geopolymer Composites

Bone ash reinforced geopolymer composites (Bhuiya *et al.*, 2021)

Potassium-based, geopolymer composites have been made with metakaolin and Mymensingh clay from Bangladesh, which was heated and decomposed at 750°C for 2 h to form ~60% metakaolin and ~40% quartz plus impurities. A synthetic analog of the natural calcined clay was made by adding ~40% quartz particulates to metakaolin. By analogy with bone china, bone ash or calcined hydroxyapatite ($5\text{CaO} \cdot 3\text{P}_2\text{O}_5$ or “HA”) particles, having a Ca:P ratio of 3.3 to 1, were added to make the two types of

Table 3 Summary of flexure strengths of metakaolin-based geopolymer composites with organic or biological reinforcements

Reinforcement	wt% Additions	Flexural strength (MPa)
Polypropylene chopped fibers (1/2")	2.5	14.5
Polypropylene chopped fibers (1")	2.5	15
Polypropylene chopped fibers (2")	2.5	18.3
Cork particles	60	2.5 (0.75% strain to failure)
<i>Abaca</i> (banana leaf fibers or "Manila hemp")	8	52
<i>Corn husk</i> fibers	13	7.6 (7% strain)
Rice husk stems in <i>rice husk silica-based</i> GP	7	12.4
<i>Jute</i> weave	30	20.5
Colombian <i>fique/sisal</i> (unidirectional)	50	11.4
Amazonian <i>malva</i> (unidirectional)	5.5	31.55
Amazonian <i>curaua</i> (unidirectional)	8.3	18.86
Amazonian <i>Guadua angustifolia</i> chopped bamboo dispersed in Amazonian clay-based geopolymer	5	7.5
Bangladeshi <i>coconut coir</i>	10	7.50
Bangladeshi <i>palm tree coir</i>	10	7.61
Hemp felt	3.8	17.4
Flax felt	3.8	17.3

Note: From Kriven, W.M., 2018. Chapter 5.9 – Geopolymer-based composites. In: Beaumont, P.W.R., Zweben, C.H. (Eds.), *Comprehensive Composite Materials II*, vol. 5. Oxford: Academic Press. pp. 269–280. Sankar, K., Kriven, W.M., 2017. Geopolymer reinforced with E-glass Leno weaves. *J. Am. Ceram. Soc.* 100 (6), 2492–2501. Available at: <https://doi.org/10.1111/jace.14783>.

natural and synthetic geopolymer-based composites. For less refractory additions, dicalcium phosphate ($2\text{CaO} \cdot \text{P}_2\text{O}_5$ or "DCP") particles, having a Ca:P ratio of 2:1, were also added to another set of the two types of geopolymers composites.

The composites made were as follows, corresponding to Fig. 9:

- (1) Potassium geopolymer with metakaolin (MetaMax, BASF Corp) - KGP (MT).
- (2) Potassium geopolymer with metakaolin from Mymensingh clay - KGP (MW).
- (3) Potassium geopolymer from metakaolin clay and containing 40% quartz -KGP (MW-SYN).
- (4) Potassium geopolymer reinforced with hydroxyapatite - HA.
- (5) Potassium geopolymer reinforced with dicalcium phosphate - DCP.

Their compressive and 3-point flexural strengths were measured at ambient temperatures for all of the geopolymer composites. The HA or DCP reinforced geopolymer composites were also heat-treated to $1150^\circ\text{C}/1\text{ h}$ and converted to their mineralogical analogs. Their mechanical properties of compressive and 3-point flexural strengths were again measured. Flexural strengths of $22.42 \pm 11.0\text{ MPa}$ and $31.97 \pm 8.3\text{ MPa}$ were measured in $1 \times 1 \times 10\text{ cm}^3$ heat-treated geopolymer bars reinforced with 10 wt% of DCP and in geopolymer reinforced with 10 wt% DCP + 40 wt% quartz additions, respectively. The room temperature compressive strength of K-based metakaolin-derived geopolymer was 49.3 MPa. Significant improvements to ambient temperature properties were observed due to the self-healing effect of the flowing amorphous DCP, whose presence was verified by SEM (Fig. 10).

SEM micrographs of pure geopolymer at room temperature revealed fully reacted microstructures, while those in geopolymer composites showed reinforced particles in the consolidated geopolymer matrix. The higher flexural strength in thermally treated samples containing 15 wt.% DCP was attributed to the development of phosphate glass, which sealed dehydration and crystallization cracks, as well as development of crystalline phases of leucite, quartz, monetite and tuite in the geopolymer matrix.

The geopolymer samples after thermal treatment exhibited water absorption within 0.03%–0.5%, compared with those at room temperature except in KGP(MT)-15DCP (9.32%). The higher water absorption in KGP containing 15 wt.% DCP was attributed to higher grain size and higher refractoriness in the DCP. Potassium based, metakaolin derived GP containing 15 wt% DCP could be further studied for possible biomedical applications as a bone-like implant material subject due to forming an apatite layer on the porous geopolymer composite surface.

Amorphous self-healed, basalt fiber-reinforced, geopolymer composites (Keane et al., 2021)

The melting and bonding of a molten glass phase dispersed into a surrounding potassium activated, metakaolin-based geopolymer (KGP) matrix, produced a self-healing effect on a dehydrated and cracked geopolymer matrix (Keane et al., 2021). The addition of more reinforcements produced a self-glazing effect on the composite, thereby sealing the surface cracks. At temperatures up to 900°C , the geopolymer composite containing chopped basalt fiber (from Technobasalt[®], Kiev, Ukraine) remained amorphous and a low melting glass frit ($T_m = \sim 800^\circ\text{C}$) flowed into dehydration cracks in the geopolymer matrix. This type of composite could be described as "amorphous self-healed geopolymer (ASH-G)". The room temperature flexure strength of samples heat treated up to 900°C significantly increased after adding glass frit, owing to the "self-healing" effect. At 950°C , the K-based geopolymer started to form crystalline leucite ceramic of composition $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$ or KAlSi_2O_6 which is stable up to its melting temperature of 1693°C .

Fig. 9 Comparison of 3-point flexural strength of composites heat treated at 1150°C/1h. Synthetic metakaolin containing 40 wt% quartz particulates (MW-Syn) were stronger than metakaolin-based (MT) composites containing DCP. Their high temperature properties are superior to RT properties due to amorphous self-healing glass formation (ASH) from the DCP phosphate glass. The optimum DCP content was 10 wt% which gave flexure strengths of ~32 MPa after heat treatment.

Fig. 10 SEM micrograph of K-based, metakaolin derived geopolymer containing 15 wt.% of dicalcium phosphate after being heated and cooled at 5°C/min to 1125°C with a 1.5-h hold time.

By 1000°C, the geopolymer converted to a ceramic, but the basalt fibers remained intact, and the melted glass frit flowed into cracks formed due to crystallization and liquid phase sintering and sealed the cracks. Thus, this type of composite could be described as an “amorphous self-healed ceramic (ASH-C)”. 1150°C was determined to be the optimum heat treatment temperature since at 1200°C the basalt fibers melted and the strength of the reinforcement would have been lost in the composite. In samples heat treated at 900°C a maximum room temperature flexure strength of 4.5 MPa was achieved. Furthermore, in samples heat treated at 1150°C a maximum room temperature flexure strength of 6 MPa was measured. A Weibull statistical analysis was performed showing how the amorphous self-healing effect of the glass frit significantly improved the room temperature flexure strength of the heat-treated geopolymer and ceramic composites. Thus, geopolymer composites have been developed that can be scaled up and fabricated by high shear, similar to for cements, but can have the properties of ceramics after in situ exposure to high temperatures up to 1200°C (Figs. 11 and 12).

Tailorable Thermal Expansion Ceramics Derived From Metakaolin-Based, Alkali Activated Geopolymers

The thermal expansion and phase transition behavior in the leucite-pollucite compositional series synthesized by geopolymer crystallization have been shown to differ due to structural changes in the aluminosilicate framework (Stevenson and Kriven, 2021). Crystallographic intra- and inter-tetrahedral distortion mechanisms have been proposed to explain the changes in thermal expansion and phase transitions. Tetrahedral rotation and bond swinging in tetragonal phases led to a rapid expansion and

Fig. 11 Room temperature three-point flexural strength of “1/4” chopped Technobasalt fiber-reinforced KGP, with and without 7.5 wt.% glass frit, after heat treatment at 7.5°C/min ramp rate and 2 h hold time. This illustrates the role of amorphous self-healing (below 1000°C ASH-G) and (above 1000°C ASH-C) in improving the flexural strengths of composites.

Fig. 12 Potassium-based geopolymer composite containing glassy phase (KGP ASH-C) heated treated at 1200°C/2 h showing melted glassy phase clearly visible in the bottom right hand corner of this SEM micrograph. From Keane, P.F., Foltz, J.S., Chadha, V., Marsh, C.P., Kriven, W.M., 2021. Amorphous self-healed, chopped basalt fiber-reinforced, geopolymer composites. *J. Am. Ceram. Soc.* 2021b Available at: <https://doi.org/10.1111/jace.17648>. (In press).

distortion of the unit cell that accelerated with temperature, culminating in a phase transition to cubic symmetry. Elongation of coordination bonds in cubic leucite and mixed-cation systems caused moderate expansion of the cell that decelerated with temperature. Cubic pollucite exhibited a constant, low thermal expansion across the temperature range probed. For application as environmental barrier coatings (EBCs), suppressing the phase transition in leucite is important to avoid the associated discontinuous volume change. The phase transition temperature was suppressed below room temperature in materials containing greater than 40 mol% cesium. Samples with greater than 80 mol% cesium exhibited very good thermal expansion matches to the SiCf/SiC ceramic matrix composite (CMC) system with higher melting points than current alternatives (Fig. 13).

The range of thermal expansion values attainable in the $K_xCs_{1-x}[AlSi_2O_6]$ system offers reduced CTE mismatch with SiCf/SiC compared to rare earth-based systems. For the successful application of these materials as EBCs, however, further investigation into their reactivity with contaminants in the combustion environment, namely calcium magnesium aluminosilicates, and resilience to thermal cycling is critical.

Low Energy Fabrication Routes to Ceramic Powders

Several potential applications as well as fabrication routes to ceramic powders and polycrystalline ceramics via the geopolymerization route have been identified by Bağcı *et al.* (2014, 2016, 2019). By carbothermal reduction, silicon carbide can be cost effectively synthesized from metakaolin-based geopolymer precursor containing carbon additions as a reducing agent. Crystallization of silicon carbide from geopolymers represents a novel approach to forming highly reactive, ceramic powders. Using the nanoporous, nanoparticulate geopolymer, and a higher amount of nanosized carbon gave rise to improved reaction between constituents. While the commercial Acheson process needs heating at 2500°C for ~2 days, the process described in the work of Bağcı *et al.*, 2019 produced a 97% conversion to SiC starting from K-based geopolymer and excess carbon, producing phase pure silicon carbide, at 1600°C in 2 h. This systematic research compared Na, K, and Cs geopolymers as precursors to silicon carbide synthesis. Heating above 1400°C was sufficient to synthesize silicon carbide and its yield increased with increasing temperature in

the case of sodium based geopolymer (NaGP) and potassium-based geopolymer (KGP). Additionally, NaGP had an advantage over the KGP and cesium-based geopolymer (CsGP) in terms of high yield and phase pure, silicon carbide at $1400^\circ C$ as well as its low cost. CsGP failed to convert to silicon carbide but produced predominantly alumina instead (Figs. 14–16).

Compositionally variable, nitride crystalline phases were also successfully synthesized from metakaolin-based geopolymer precursors containing nano-carbon, via carbothermal reduction and nitridation. This geopolymer processing route is a cost-effective method whereby the nano porous nature of GPs served to improve the reaction with nano-carbon particles during carbothermal reduction. A high yield of over 95% of silicon nitride (Si_3N_4) containing two polymorphs (mainly alpha) was synthesized from sodium ($Na_2O \cdot Al_2O_3 \cdot 4.5SiO_2 \cdot 12H_2O$) and potassium ($K_2O \cdot Al_2O_3 \cdot 4.5SiO_2 \cdot 12H_2O$) precursors to mainly beta (Si_3N_4) on heating at $> 1400^\circ C$ under flowing nitrogen. Furthermore, a high yield of SiAlON (over 90%) was synthesized in the case of cesium ($Cs_2O \cdot Al_2O_3 \cdot 4.5SiO_2 \cdot 12H_2O$) precursor using only 9 mol% of excess C and the same synthesis route.

Conclusion

The field of geopolymers is a new, low energy way to make inorganic polymer materials that are intermediate between cements and ceramics. They are made under higher shear, as compared to a cement, but can have higher temperature capabilities than

cements when they set. Both alkali-activated as well as acid-activated aluminosilicates form ceramic-like bodies. Alkali activated geopolymers having nominal compositions centered around $M_2O \bullet Al_2O_3 \bullet 4SiO_2$ while the phosphoric acid activated geopolymers have compositions centered at $Al_2O_3 \bullet 2SiO_2 \bullet P_2O_5$.

The amorphous aluminosilicate results from calcination of crystalline, kaolinite-type clays (e.g., kaolinite, halloysite) of composition $(Al_2O_3 \bullet 2SiO_2 \bullet 2H_2O)$ at $750^\circ C/2$ h. The chemical reactions occur by dissolution of the amorphous aluminosilicate source, polycondensation in a highly concentrated aqueous solution, and precipitation to form a solid body. A key requirement for alkali reacted geopolymers is to have the Al atoms in five-fold coordination with oxygen atoms, forming a double bond with one oxygen atom, which causes the molecule to be in a highly strained state. These AlO_5 molecules are thus susceptible to attack by the water glass solution and hence dissolution. AlO_4^- and SiO_2 tetrahedra form in solution, upon which then polymerize and precipitate under mildly exothermic conditions up to $100^\circ C$. Since lower amounts of water than in cements are necessary and the water is "recycled" after the precipitation of the nanoparticles, the resulting inorganic polymer is stronger and more rigid than a gel and hence more like a ceramic.

The intrinsic microstructure of alkali activated geopolymers is nano porous (40 vol%, 6.8 nm diameter) and nanoparticulate (20–40 nm), having densities of ~ 1.5 g/cc. The nano regions of water dispersed in the crosslinked, polysialate molecular structure are removed on heating to 250 – $400^\circ C$, forming microcracks. However, when filler phases or reinforcements are added during polymerization, the geopolymer cross-links around them to form strong, flaw-tolerant ceramic bodies which are stable up to the crystallization temperature at $\sim 950^\circ C$ to $1050^\circ C$, for Na, K, and Cs-based geopolymers, respectively. Na-based geopolymers form nepheline ($Na_2O \bullet Al_2O_3 \bullet 2SiO_2$) plus SiO_2 glass, since the formation of jadeite ($Na_2O \bullet Al_2O_3 \bullet 4SiO_2$) requires geological pressures of 1.7 GPa and $1250^\circ C$. K and Cs-based geopolymers form leucite ($K_2O \bullet Al_2O_3 \bullet 4SiO_2$) and pollucite ($Cs_2O \bullet Al_2O_3 \bullet 4SiO_2$) under ambient pressures, however. Geopolymers based on mixtures of K- and Cs-based waterglass solutions open the way to tailorable thermal expansion geopolymers and geopolymer-derived thermal barrier or environmental barrier (TBC, EBC) coatings.

A wide variety of geopolymer composites have been made and their mechanical properties (mostly flexural strengths) have been measured. Due to the low setting temperature under ambient conditions, ceramic, metal, polymer and biological reinforcements can be incorporated. The reinforcements can be particulate, elongated or faceted-shaped particles of various sizes, chopped fibers, directional fibers, weaves or 3D meshes. The composites can be scaled up, for construction and road work purposes, as well as applied as coatings, since there is no need for firing. They can be pre-fabricated and readily shaped in plastic molds to which geopolymers generally do not adhere. Geopolymers can also readily be 3D or 4D printed due to their thixotropic rheology as a composite material.

In the case of refractory reinforcements such as ceramic particulates or chopped fibers, the microcracking results from dehydration and crystallization can be self-healed by the presence of glassy phase upon heat treatment above the melting temperature of the glass. Amorphous self-healed geopolymer (ASH-G) and amorphous self-healed ceramic (ASH-C) enable the geopolymer to retain significant strength and impermeability upon exposure to high temperatures. This self-healing pre-treatment leads the way to versatile, intermediate temperature ceramics, up to $1200^\circ C$ at present. The nanoparticulate particle sizes can be exploited as nano-diffusion distances to fabricate ultra-high temperature ceramic powders such as SiC, Si_3N_4 , and SiAlONs by carbothermal reduction and carbothermal nitridation of geopolymer-carbon mixtures at significantly reduced temperatures (1400 – $1600^\circ C$) and costs compared to current technologies. Thus geopolymers can provide a versatile new class of inorganic polymers that can lead to low energy syntheses of ceramics.

Overview: Characterization and Modelling of Ceramics and Glasses

Michael Pomeroy and Stuart Hampshire, Bernal Institute, University of Limerick, Limerick, Ireland

© 2021 Elsevier Inc. All rights reserved.

This section is devoted to modeling and characterization. Thus, it contains chapters which describe how ceramics and glass structures can be designed and understood from fundamental first principle calculations, how stable phases are and how phase diagrams can be predicted from fundamental thermodynamics. The remainder of the chapters in Section 2 describe analytical techniques commonly used for glass and ceramic materials to determine information relating to fine structure (i.e., coordination number, bond angles, bond lengths), crystal structure and microstructure.

The first three chapters cover modeling of ceramic and glass structures. The chapter by Ching outlines an exciting area of ceramics research related to ceramic genomics. He relates the use of total bond order density to not only predict formulae and structures of new ceramic materials, but also to predict mechanical properties such as moduli, Poisson's ratio and yield strength for example. Guerin *et al.* explore the modeling of ceramics in more detail and explain the use of density functional theory to extend molecular dynamics. They then exemplify this by the clarification of crystal structures and using modeling to assess ceramic elastic strain tensors, time and temperature dependent phenomena and piezoelectric charge tensors and voltage constants. The chapter by Edén relates the use of molecular dynamics simulations to develop models of glass structures in melt quenched oxide glass systems and how pair distribution and bond angle data can be obtained from such exercises. In addition, the effects of modifier ratio and type on glass structures can be readily predicted and are in excellent agreement with MAS-NMR analyses. The final chapter in the section on prediction is the Computation of Phase diagrams. This chapter gives an excellent background to the fundamental thermodynamics associated with the calculation of phase diagrams and examines the CALPHAD methodology in some detail. The chapter then goes on to look at calculated binary and ternary phase diagram examples.

Murtagh and Venopaul initially review what they call “static characterization techniques” for ceramic powders e.g. chemical composition, phase assemblage, particle size distribution, specific surface area, bulk density etc. They then go on to indicate that whilst these parameters may be of great use in terms of characterizing a small batch, when it comes to fully understanding inter-relationships between powder parameters and the microstructure of a processed ceramic then additional factors must be considered. These additional factors are related to consistency of mixed powder flow and how various factors, such as humidity, affect it. In addition, powder permeability and powder compressibility can be affected by so-called dynamic powder characteristics. Thus, this original approach to powder characterization has greatly assisted the understanding of particle behavior in powder mixtures during processing into fired components.

Four chapters follow which are related to fine structure (bond lengths, coordination number) and crystal structure analysis. McMillan's chapter on vibrational spectroscopy covers the analysis of chalcogenide, silicate, alumino-silicate, phosphate, borate and fluoride glasses. Of particular interest is the ability of the IR/Raman techniques described to provide fine structure detail of glasses. Thus, for example, McMillan shows how peak positions change with the number of bridging oxygens in silicate glasses as well as how the characteristic spectra for borate glasses change as compositional changes allow boron to change its coordination from III to IV. The chapter by Gao on Magic Angle Spinning (MAS) – NMR, gives a very good introduction to the background behind the technique. Following this introduction, Gao then goes on to give examples of the use of MAS -NMR in ceramics and glass research, paying particular attention to ^{29}Si , ^{31}P , ^{19}F , and ^{27}Al analyses. Such analyses allow fine structure analysis of ceramics and glasses (e.g. determination of coordination number). Thus for example, the relative amounts of aluminum acting as a glass modifier (Al (V), Al (VI)) compared to that acting as a glass former (Al(IV)) can be readily obtained using MAS-NMR techniques. Additionally, MAS-NMR is the only technique which can readily confirm the presence of fluorine in hydroxyapatite and that it substitutes in OH^- positions in the lattice. In his chapter on X-ray diffraction, Misture outlines the use of X-rays for Pair Distribution Function (PDF) determination. This aspect of X-ray analysis is of great use in determining nearest neighbor atoms in ceramics, as well as glasses. Associated structural modeling assists in the interpretation of the PDF data. The chapters by Misture and Gonon deal in detail with X-ray diffraction (XRD) and its typical applications in ceramic science. Thus, both chapters, but particularly that by Misture, detail the interaction of X-rays with crystals, the fundamentals of structure, phase identification, quantitative phase analysis, unit cell indexing, refining lattice parameters, Rietveld refinement, preferred orientation, residual stress and crystallite size. Gonon's chapter provides excellent case studies of the use of XRD which reinforce and extend the fundamental information in the technique descriptions.

Fetzer *et al.* explain the basics behind transmission electron microscopy (TEM) and how the technique, which has 10^{-10} m resolution, can be used to examine 20–100 nm thick samples. Such thin samples are made using specimen preparation techniques such as dimpling/argon ion thinning, tripod polishing (tapered section) or focused ion beam milling. The chapter gives a concise account of electron beam generation and control, how the electron beam interacts with specimens facilitating electron contrast and thus imaging. Electron diffraction and dark field imaging are explained as well as imaging contrasts arising from thickness effects, bends in specimens or defects (e.g. dislocations). Electron diffraction is explained extremely well in the chapter of Fetzer *et al.* and enables the early researcher to understand how TEM can be used to determine crystallographic properties of various phases. The final section in the chapter deals with high resolution imaging and introduces the concept of being able to identify atom types in atom columns in engineering and electronic ceramics. Cookman *et al.* extend this knowledge base in their chapter on high

resolution analytical electron microscopy of ceramics and glasses. This chapter looks at the use of aberration corrected scanning transmission electron microscopy (STEM) and how chemical contrast can be generated and mapped by annular dark field STEM as well as the relatively new differential phase contrast imaging method. In addition to chemical/phase contrast the chapter also addresses how energy dispersive X-ray analysis (EDX) and electron energy loss spectroscopy (EELS) can be used to identify the location of specific elements with very high spatial resolution, facilitating atomic resolution images of atom positions on specific atomic planes. Another exciting possibility arising from EELS analysis is its use in fine structure analysis. Cookman *et al.* report the use of EELS in understanding differences in bonding between phase separated regions in an alumino-silicate glass. Stewart and Kolb's chapter on 3D electron crystallography is an overview of this exciting new approach to crystallographic analysis. Having established the background to the technique, the authors then go on to show how it can be used to investigate the crystallography of nanocrystalline materials including glass ceramics.

Whilst the chapter by Pomeroy on preparation of specimens for microstructural examination may seem very practically oriented, it is very interesting to note that very, very few journal papers explain the steps taken to produce a polished and etched specimen for microstructural analysis. This can be exceedingly frustrating for a new researcher who may be working in relative isolation and cannot benefit from the experience of a group. The chapter thus gives the background to choosing and using the various consumables (sectioning saws, mounting media, grinding and polishing platens and abrasives) involved in preparing a sample for microstructural analysis. It also reviews the various etching methods and the ceramics they are typically used for. Pomeroy's chapter on scanning electron microscopy of ceramics and glasses gives an introduction to the current scope afforded by SEM technology to investigate the microstructure of ceramics. Having described the basic anatomy of a SEM and beam specimen interactions, this chapter goes on to look at how image contrast is generated and how that results in image generation. Of particular interest is compositional imaging which allows an understanding of the development of phase assemblage in glass ceramics for example. This chapter also examines the analysis of X-rays emitted from specimen surfaces during SEM examination. Mecholski Jr. describes the fractography of brittle materials and how it contributes to understanding brittle failure and the failure of materials with reasonable toughness due to R-curve behavior. The chapter also explains how fractography can determine not just the origin of failure but also whether the failure results from a processing defect or overload.

The chapter by Pomeroy on thermal analysis of ceramics and glasses deals with thermogravimetry, differential thermal analysis/differential scanning calorimetry and dilatometry. Each technique is briefly described and then examples related to the understanding of ceramic and glass science are given. Thus, precursor decomposition, binder loss and oxidation of ceramics are dealt with under thermogravimetric analysis; differential thermal analysis/differential scanning calorimetry methods deal with the determination of glass properties (e.g. glass transition temperature, inference of effect of temperature on glass viscosity, glass nucleation and crystallization temperatures) and temperatures and energies associated with phase transformations; the part of the chapter dealing with dilatometry covers sintering rate analysis, measurements of coefficients of thermal expansion as well as glass transition and dilatometric softening temperatures and temperatures at which ceramics undergo phase transformation. Sukenaga and Shibata look in detail at the measurement of the viscosity, density, and surface tension of molten oxides using a variety of techniques. They discuss the use of the rotating cylinder and levitation methods for viscosity measurement and then go on to look at the measurement of the density of molten oxides using Archimedian, sessile drop and levitation methods and how surface tension can be measured using a ring technique, the maximum bubble pressure technique or a levitation method. Extremely useful information can be extracted from the data obtained which can contribute to advanced glass processing and the understanding of composition – structure – property relationships in such systems.

Ceramic Genomics: Total Bond Order Density

Wai-Yim Ching, University of Missouri-Kansas City, Kansas City, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

The word geno or genome originating from biology has been pervasive in materials science discipline within last two decades. This started at the initiation of materials genome project at the federal level that follows the same approach of the Human Genome Project in the biomedical community decades ago, which resulted in the now mature discipline of bioinformatics (Service, 2015). Since ceramic materials have many outstanding properties, functionalities and applications, it is not surprising the ceramic geno becomes a popular topic at conferences and in scientific arena. This is consistent with the general concept that the gene is the essence that controls what are evolving from it to its offspring or derivatives. Thus seeking the gene inevitably becomes the Holy Grail in pursuing the fundamental origin of material properties.

In all materials, there are always different metrics for its characterization on different aspects of its properties. For example, experimentally measured quantities such as mass density, melting point, refractive index, hardness, fracture toughness, ductility etc. They can related to the genes based on their atomic compositions, arrangements, interactions, and their thermodynamic states etc. Non-measurable quantities are generally inferred from experiment, theory, experience, intuition or perceptions. These include the position in the Periodic Table, atomic number, atomic radius, electronic configuration, temperature, pressure, lattice parameter, diffraction pattern, and much more. Many of these quantities can be obtained from simple or elaborate measurements. They can also be obtained from empirical and ab initio calculations. The development of the density functional theory (DFT) (Hohenberg and Kohn, 1964; Kohn and Sham, 1965) and the rapid increase in computational power have accelerated the computational trend. It is now possible to obtain accurate results on properties of materials and even predict experimental observations. In the last few years, I have been advocating the use of total bond order density (TBOD) as a single quantum mechanically derived metric that can be used to assess many of the materials properties. Total bond order (TOB) is the sum of all pairs of bond order values. When normalized by the volume of the system under consideration, we obtain the TBOD that represent the internal cohesion of the material and is related to materials geno in some way. It could play a crucial role in materials informatics if large database of TBOD for different classes of materials are available to facilitate predictions.

In recent years, information collection, classification, analysis, interpretation, utilization and dispersion have emerged as an interdisciplinary research platform involving computer science, information science, and various disciplines in science and arts such as physics, chemistry, biology, medicine, materials engineering, earth science, design technology, education, social science, legal community etc. In particular, materials informatics has developed into a flourishing field of study (Vapnik, 2013; Ching, 2016; Rajan, 2005). It aims to find more efficient ways of solving scientific problems related to all kinds on materials using large databases. This ultimately connects to fashionable subject of machine learning (ML) and artificial intelligence (AI) (Raccuglia *et al.*, 2016; Cubuk *et al.*, 2015; Ramprasad *et al.*, 2017; Sun *et al.*, 2017b). In this regard, the input will be some key parameters called descriptors and when feed into carefully designed equations and sophisticated algorithms, it can predicate unknown materials with desired structure, composition and properties. There are many different ways of collecting large data and building powerful databases for applications such as demonstrated by (Tancrét *et al.*, 2017; Islam *et al.*, 2018; Lookman *et al.*, 2017; Xue *et al.*, 2016). More recently, large amounts of data may be obtained through calculations using different computational methods and packages based on different theories. TBOD mentioned above could be one of such descriptors that could play a dominating role.

In this chapter I start with a short description of the methods and approach used in calculating the TBOD. The focus is on the application of TBOD to different materials beyond just ceramics and glasses based on the data obtained from computation. The database constructed can be used in ML strategy to facilitate new materials discovery, In particular, we point out the use of TBOD in complex metallic alloys and glasses, which have very different types of bonding than in ceramic materials. We also show the very promising progress in applying it to complex biological materials and their interfaces with inorganics where the weak but ubiquitous hydrogen bonding (HB) are prevailing. Most of the work described here have been published within the last few years but many of them are from projects currently in progress.

Methods and Approach

Crystal Structure and Supercell Models

In any experimental work in materials science, the most important starting point is the availability of material samples. In fact, without the real material samples, there would be no materials science. It is the same in computational research, we need theoretical samples. In case of crystalline materials, they can be directly obtained from many experimental measurements deposited in well documented database such as: Cambridge Crystallographic Data Center (CCDC) (see "Relevant Websites sections"), protein data bank (PDB) (see "Relevant Websites sections") The Materials project (see "Relevant Websites sections"). They can be further refined or optimized if necessary using different methods and level of accuracy. In case of hypothetical

materials, newly proposed structures or disordered materials such as glasses, we need to construct plausible models based on which simulations can be carried out. This is tantamount to theoretical sample preparation, the starting point similar to experimental research. For glasses or complex materials, we need to use supercells with at least ~ 1000 atoms and fully relax the structure which could be computationally very expensive. Depending on the nature of the problem, the complexity of the system and the properties to be computed, smaller supercells may be used without compromising the key conclusions. Most of the supercells maintain the periodic boundary condition to mimic the infinite solid or liquid materials. Small supercells may introduce inaccuracy due to the size effect. In case of complex bimolecular systems, one can simply put the molecules inside a large cell and solvate it with appropriate number of water molecules if necessary for large-scale simulations.

An important point that must be emphasized is that the supercell models must be fully relaxed based on energy minimizations. The quality of electronic structure calculation depends on the atomic positions in the model based on which the TBOD is evaluated. There are many DFT-based computational packages for structural relaxation and they need not to be the same one used in the electronic structure calculations since they have different focuses. One is for the preparation of the theoretical sample, the other is for the calculation of electronic structure and bonding. We use the Vienna Ab initio simulation package (VASP) (see “Relevant Websites sections”) for structure relaxation. VASP is one of the most popular packages using pseudopotential and plane wave expansion. It is highly accurate, efficient and with many different choices for the exchange correlation potentials. The accurate atomic structure and the volume of the cell control the accuracy of the TBOD. Other similar packages such as Quantum Espresso (see “Relevant Websites sections”), ABINIT (see “Relevant Websites sections”), Amsterdam Density Functional (ADF) (see “Relevant Websites sections”) and Gaussian-09 (see “Relevant Websites sections”) and many others are also popular and can be used for structural relaxation. We will illustrate this strategy with applications to different materials in later sections.

Electronic Structure and Interatomic Bonding

The evaluation of TBOD for a crystal or a supercell model starts with the calculation of electronic structure using *ab initio* DFT-based methods. While many different types of DFT calculations on systems large and small are available, we will focus of a method we developed in house for such calculations, the orthogonalized linear combination of atomic orbitals (OLCAO) method (Ching and Rulis, 2012). The VASP-relaxed structures are used as input. The OLCAO method uses atomic orbitals for the basis expansion and is highly efficient as well as economic, especially for large complex systems. In most OLCAO calculations, a more localized minimal basis (MB) set is used for the calculation of effective charges Q_α^* and the bond order (BO) values $\rho_{\alpha\beta}$ between a pair of atoms (α, β) using Mulliken population analysis scheme (Mulliken, 1955a,b).

$$Q_\alpha^* = \sum_i \sum_{m,occ} \sum_{j,\beta} C_{ix}^m C_{j\beta}^m S_{ix,j\beta} \quad (1)$$

$$\rho_{\alpha\beta} = \sum_{m,occ} \sum_{j,\beta} C_{ix}^m C_{j\beta}^m S_{ix,j\beta} \quad (2)$$

In Eqs. (1) and (2), $S_{ix,j\beta}$ are the overlap integrals between the i th orbital in the α th atom and j th orbital in the β th atom. $C_{j\beta}^m$ are the eigenvector coefficients of the m th band for the j th orbital in the β th atom. We usually calculate the partial charge ΔQ or the charge transfer for each atom which is the deviation from neutral charge (Q^0) and the effective charge (Q^*) of the same atom i.e., $\Delta Q = Q^0 - Q^*$. Accurate partial charge is extremely important in interpreting many of material properties and their functionality especially in biomolecular systems. As an example, the MB set used in the study of the pyrophosphate crystal ($K_2Mg(H_2P_2O_7)_2 \cdot 2H_2O$) (see Section 3.1 below) have the following atomic configurations: P: $1s^2 2s^2 2p^6 3s^2 3p^3$; Mg: $1s^2 2s^2 2p^6 3s^2$; K: $1s^2 2s^2 2p^6 3s^2 3p^6 3d 4s^1$; O: $1s^2 2s^2 2p^4$ and H: $1s^1$. A full basis (FB) set that has one more shell of atomic orbitals in the basis than the MB is used for the calculation of self-consistent potential, total density of states (TDOS), and partial density of states (PDOS), band structure and optical properties. The BO $\rho_{\alpha\beta}$ in Eq. (2) provides a quantitative measure for the strength of the bond between atom α and β . The summation of all BOs normalized by the cell volume gives us the TBOD which is a single metric to assess the internal cohesion in the crystal. TBOD can be resolved into partial components or the partial BO density (PBOD) from different types of atomic pairs, or different groups of atoms in the structural units in the crystal or the supercell. This decomposition of TBOD to PBOD is very useful for proper interpretation of the results on the interatomic interactions as will be illustrated in many examples later in Section 3.

There are many other methods and theories for the bond order or effective charge calculations (Manz, 2017). Some of these methods can be very accurate and elaborate but are generally limited to smaller crystals or molecules. Therefore, there is always a tradeoff between efficiency and accuracy in material-related data generation using computational approach. It should be emphasized that the calculations of PC and BO is basis dependent. In many instances, even the definition of BO and PC can be different in different DFT methods, or computational packages. It is quite meaningless to compare BO or TBOD obtained using different methods or using different bases. Our experience of using the OLCAO method based on Mulliken scheme of BO evaluation is very satisfactory and consistent. It is most natural to use atomic wave functions in the basis expansion and extremely efficient for application to large complex systems.

Physical Properties Calculation

For the TBOD to be claimed as a material geno, it must be correlated with the physical properties calculated or measured. These include interatomic bonding, spectroscopic and vibrational properties, elastic and mechanical properties, and much more. Most importantly, it should be applicable to all materials systems, ordered or disordered, perfect or defective. Since TBOD and its partial components the PBOD measure the internal cohesion of the material and their constituent components, correlation with the mechanical properties would be the most obvious. Other properties such as the spectroscopic properties are less important since they are usually related to excitation of the electron, from the valence band or from deep core levels such as in electron energy loss spectroscopy (ELNES) and x-ray absorption near edge spectroscopy (XANES). Mechanical properties are usually reflected in their elastic constants, modulus values, and Poisson's ratio and other parameters derived for them. We will illustrate such correlations in many examples later.

For mechanical properties calculation, we do not use the OLCAO method but use the fully relaxed structure from VASP or other computational packages. This is the vivid example that in computational materials research, using the combination of different methods in order to take their respective advantages is most effective. For elastic properties calculation, we use the stress (σ_j) vs strain (ϵ_i) response analysis scheme (Nielsen and Martin, 1983; Yao *et al.*, 2007). In this scheme, we apply a small strain ϵ (usually $\pm 0.5\%$) to the fully relaxed structure to obtain the elastic coefficients C_{ij} and compliance tensor S_{ij} ($i, j = 1, 2, 3, 4, 5, 6$) in solving the set of linear equations. From the calculated C_{ij} , other mechanical properties such as bulk modulus (K), shear modulus (G), Poisson's ratio (η), Young's modulus (E) are obtained using Voight-Reuss-Hill (VRH) polycrystals approximation (Reuss, 1929; Hill, 1952). Additional related mechanical properties such as elastic anisotropy, hardness, yielding strength etc. can be separately calculated if desired.

Application of TBOD to Ceramic Materials

Oxides, Nitrides, Carbides and Phosphates

Most ceramics are oxides, nitrides, carbides, borides or phosphides. They are all covalently bonded and may have ionic characters. The bond order values in these crystals are clear and well defined. Here we cite some of the examples for the application of TBOD to these most fundamental ceramics. Fig. 1 shows the crystal structure of three basic silicon nitrides, α -Si₃N₄, β -Si₃N₄ and γ -Si₃N₄ together with an oxynitride crystal Si₂N₂O. γ -Si₃N₄ is also called the cubic Si₃N₄ in the spinel structure. The electronic structure of these crystals have been investigated by us long time ago (Ren and Ching, 1981; Xu and Ching, 1995; Ching *et al.*, 2000, 2002; Zerr *et al.*, 2006; Ching, 2000) but their BO and TBOD have been calculated only recently and listed in Table 1. As can be seen that Si₂N₂O have less TBOD due to the presence of weaker Si-O bonds compare with Si-N bonds, and γ -Si₃N₄ has the largest TBOD because of additional bonding from the strong Si-N bonds at the octahedral site of Si. It is also interesting to see that α -Si₃N₄ has larger TBOD than β -Si₃N₄ mainly because it has shorter Si-N bond length (BL) hence larger BO values.

Figs. 2 and 3 show the structures of the two most basic silicon oxides (stishovite and α -quartz), three forms of TiO₂ (rutile, anatase and brookite) as well as two most well-known ternary oxides, spinel Mg₂SiO₄ and perovskite SrTiO₃, and lastly four of the many polymorphs of SiC (3C, 2H, 4H, 6H). Their electronic structure and properties have been investigated by us long time ago (Li and Ching, 1985; Ching, 1986; Xu and Ching, 1995; Mo and Ching, 2001, 1995; Ching *et al.*, 2006b). However, the TBOD for these crystals were not calculated since TBOD is a relative new concept introduced in recent years. Nevertheless, they can be calculated very easily and could be part of the valuable parameters in the database for interpretation of more complex structures. In Table 2, we list the TBOD and PBOD for these 11 crystalline of oxides and carbides. The silicon carbides have the same composition but different structures. As can be seen from their TBOD and PBOD values in Table 2, they reveal some of the common and well-known facts. The most noticeable is that the high-density stishovite SiO₂ has its TBOD 2.64 times larger than alpha quartz, since it may be the hardest material known second only to diamond. In TiO₂, The most common phase rutile has the highest TBOD. The perovskite SrTiO₃ has a higher TBOD than the spinel Mg₂SiO₄ and the four polymorphs of SiC have very similar TBOD indicating the stacking layers in the hexagonal structure do not make much difference in terms of crystal strength. These results illustrate the power and utility of TBOD as a ceramic geno for ceramic crystals with different structures, symmetries and compositions.

Next we focus on a relatively complex crystal pyrophosphate K₂Mg(H₂P₂O₇)₂ · 2H₂O with five different atomic species studied recently (Adhikari *et al.*, 2017). Fig. 4 shows the crystals structure of this pyrophosphate crystal which is far more complicated than other not so simple phosphate crystals such as aluminum phosphate (AlPO₄), potassium titanyl phosphate (KTP, KTiOPO₄), calcium pyrophosphate dihydrate ((Ca₂P₂O₇) · 2H₂O), hydroxyapatite (HAP, Ca₁₀(PO₄) · 6(OH)₂) and many others. Our result shows the complex interplay of different bonding between specific local structures and compositions that can result in large differences in reactivity and interaction which are rare in other classes of inorganic crystals. We divide this pyrophosphate crystal into three structural units: H₂P₂O₇ is the most important and dominating unit. The other two are the cationic groups of metals and the water molecules. The strong P-O bond in P₂O₅ contribute most to TBOD but O-H, N-H bonds including hydrogen bond (HB) also play an important part. All these complex bonding affects their physical properties. More importantly, this work showed that the experimentally reported structure was not sufficiently accurate resulting in unrealistically short O-H bonds that were rectified with full-scale optimization of the crystal structure. As expected, the TBOD of the relaxed crystal is slightly higher than that of the measured structure (Adhikari *et al.*, 2017).

Fig. 1 Ball & stick figures for three Si_3N_4 crystals (a) $\alpha\text{-Si}_3\text{N}_4$, (b) $\beta\text{-Si}_3\text{N}_4$, (c) $\gamma\text{-Si}_3\text{N}_4$ and (d) $\text{Si}_2\text{N}_2\text{O}$ crystal.

Table 1 TBOD, PBOD for the three Si_3N_4 crystals and $\text{Si}_2\text{N}_2\text{O}$ crystal

Crystal	Bond	TBO (electron)	TBOD (electron/Å ³)	PBO (electron)	PBOD (electron/Å ³)
$\alpha\text{-Si}_3\text{N}_4$	Si-N	16.7532	0.0560		
$\beta\text{-Si}_3\text{N}_4$		7.5032	0.0512		
$\gamma\text{-Si}_3\text{N}_4$		33.71840	0.07143		
$\text{Si}_2\text{N}_2\text{O}$	Si-N	5.2596	0.0432	4.1316	0.0339
	Si-O			1.1280	0.0092

The above limited examples on the calculation of TBOD in oxides, nitrides, carbides and phosphates can be extended to many other ceramic phases or explore new phases where the TBOD can be an extremely useful parameter, the ceramic geno. A specific example on the allocation to a model of complex intergranular glassy film in $\beta\text{-Si}_3\text{N}_4$ will be discussion in Section 3.6.

Max Phases

In this section, we present the genomic approach to the stability, elastic and electronic properties of a very important class of layered ternary compounds called MAX ($\text{M}_{n+1}\text{AX}_n$) phases (Barsoum, 2013). Within the last ten years, we have made systematic calculations on a large number of MAX phases and their properties (Mo *et al.*, 2012; Ching, 2016; Ching *et al.*, 2013; Li and Ching, 2014; Mo *et al.*, 2014; Dhakal *et al.*, 2015; Wang *et al.*, 2013). Here M stands for a transition metal, A is a group III, IV, V, or VI element with Al the most common and X is either C or N with $n = 1-5$. Fig. 5 shows the sketch for the MAX crystals with $n = 1, 2, 3, 4$. A large database of 665 viable crystals with $\text{M} = \text{Sc, Ti, Zr, Hf, V, Nb, Ta, Cr, Mo}$; $\text{A} = \text{Al, Ga, In, Tl, Si, Ge, Sn, Pb, P, As, S}$ and, $\text{X} = \text{C or N}$ was constructed and various correlations among and between them were fully explored (Aryal *et al.*, 2014). It is shown that the key parameter is TBOD and its partial components PBOD. They could explain many correlations with mechanical properties and the role played respectively by M, A, X. Detailed analysis of various correlation plots shows that there is a clear correspondence between bulk modulus K and TBOD, especially with the M-A even though the M-X PBOD makes the largest contribution to the TBOD. The correlation becomes less clear for Shear modulus G and other mechanical parameters. These correlations also show a marked difference between the carbides and nitrides, and that Sc as a metal is an exception in many of these trends.

This large database is also used to test the efficacy of data mining algorithms and statistical machine learning approach for materials genome. It is shown that by using 50% of the electronic structure data, we can predict the mechanical parameters of the other 50% data quite accurately with a correlation coefficient of over 80%. The TBOD is the key descriptor that controls the predictability (Ching, 2016). We further identified several thermodynamically stable new MAX phases that have never been synthesized in the laboratory or theoretically investigated. All the experimentally verified MAX phases passed the screening using

Fig. 2 Ball & stick figures for six oxides: (a) stishovite SiO_2 , (b) α -quartz, (c) rutile, (d) anatase, (e) brookite (f) Mg_2SiO_4 , (g) SrTiO_3 .

the TBOD as a key parameter. **Table 3** shows the TBOD for the 68 MAX phases in the database that were confirmed to exist. The same data are plotted in **Fig. 6**. Their TBOD generally lie between 0.022 and 0.049 ($\text{e}/\text{\AA}^3$), consistent with their properties, in that they behave like metals and ceramics. Most of these are 211 phases and there are far more MAX oxides than nitrides. It is also interesting to note that Sc_2InC has the smallest TBOD among these 68 phases. It has been pointed out in [Aryal et al. \(2014\)](#) that MAX phases with $M = \text{Sc}$ have been outliers in many of their properties.

C-S-H Cement Crystals

Cement and concretes are important construction and building materials worldwide. They have very complex composition and disordered structures with several known crystalline phases as ingredients ([Richardson, 2008](#)). Calcium silicate hydrate (C-S-H) is the main binding phase of Portland cement, which is the most prominent and main construction material in the world. Following the earlier calculations on some of these complex C-S-H phases such as Jennite and Tobermorite ([Dharmawardhana et al., 2013](#)), we studied the electronic structure and bonding of a large subset of C-S-H minerals with known crystal structures ([Dharmawardhana et al., 2014](#)). Our results revealed the contributions from a wide range of bonding including the hydrogen bonding to the internal cohesion of the cement crystals. It shows that TBOD is the ideal overall metric for assessing these complex C-S-H crystals and should replace the conventional practice of using C/S ratio (Ca to Si ratio) for cement materials. A rarely known orthorhombic C-S-H phase Suolunite ($\text{Ca}_2\text{Si}_2\text{O}_5(\text{OH})_2 \cdot \text{H}_2\text{O}$) is found to have the highest TBOD. **Table 4** lists the 20 crystalline C-S-H crystals used in this study and **Fig. 7** shows the crystal structure of Suolunite ([Ma et al., 1999](#)). In **Fig. 8**, we plot TBOD of these crystals vs the C/S ratio. It shows that using C/S ratio in characterizing C-S-H crystals is only approximate and need to be replaced by the more accurate quantum mechanical metric TBOD. Further detailed investigation also revealed that different types of HBs that can exist in the complex C-S-H crystals based on the TBOD and PBOD in relation to their properties ([Dharmawardhana et al., 2016](#)). Very recently, electronic structure and bonding were studied for the two very complex and highly hydrated

Fig. 3 Ball & stick figures for 4 Si carbides.

cement crystals Ettringite and Thaumasite (San *et al.*, 2018). They are rare mineral crystals with high water content. Table 5 compares their mechanical properties and TBOD with suolunite and confirms that the latter has a higher TBOD with less water content. Such detailed information on TBOD and PBOD in conjunction to various properties enable us to design new emerging cement materials and will be discussed later in the section on bio-inspired cements.

Transition Metal Carbides

In this section, we move to the application of TBOD for a specific metallic crystal between transition metal elements and C to illustrate the power and utility of TBOD. The presence of precipitate phases $M_{23}C_6$ ($M = Cr, Fe, Mo$ and W) play a significant role in the mechanical strength and creep resistance of Ni-based superalloys (Donachie and Donachie, 2002). The crystal structure of these complex carbides comprises of 116 atoms in a cubic cell of FCC lattice. We reported the investigation of the electronic structure, interatomic bonding and mechanical properties of four binary phases of $M_{23}C_6$, and $M_{23}N_6$, and six ternary phases of $(M1, M2)_{23}C_6$ (Adhikari *et al.*, 2019a). Fig. 9 shows the crystal structure of $Cr_{23}C_6$ in two different angles. Based on the results of comprehensive calculations and the evaluation of TBOD and PBOD on these binary and ternary crystals, we conclude that Fe tends to make the intermetallic structure less stable whereas W makes the crystal more compressible. The root of these observations can be traced to the size of the metal ions as well as the complex interatomic bonding of C atom with the d electrons in these metals. Fig. 10 shows the TBOD and PBOD contributions in the 10 binary and ternary $M_{23}C_6$ crystals. Interestingly, we can correlate the calculated mechanical properties in these metallic carbides with TBOD and analyze various competing factors for their interaction. Fig. 11 shows the plot of the Pugh modulus ratio G/K (Shear modulus over bulk modulus) which is used to characterize the ductility or brittleness for a material vs the TBOD, showing a very close correlation. We unequivocally confirm $Cr_{23}C_6$ to be the most stable precipitate phase with superior overall physical properties. Here, we showed the merit of using TBOD as the key parameter in assessing the metallic materials as well. Replacing C with N in these crystals does not result in any discernable difference in their properties and the TBOD of $M_{23}N_6$ is only lightly less than $M_{23}C_6$. Such investigation in using TBOD shed much light on the stabilization strategy of the presence of carbides precipitates in Ni-based superalloys.

Chalcogenide Crystals

Chalcogenide crystals and glasses are important class of compounds with relatively high refractive index. They have many unique applications in a number of industrial sectors including infrared (IR) sensors and IR optics in communications, imaging, remote

sensing and laser power delivery (Liu *et al.*, 2016; Zhang *et al.*, 2015; Dai *et al.*, 2015; Mirov *et al.*, 2015). They are used in optical fibers, solar cells and optoelectronics as well as in bio-medical applications. First-principles calculations of the electronic structure, optical and mechanical properties of 25 chalcogenide crystals: Ag_2S , Ag_2Se , Ag_2Te , As_2S_3 , As_2Se_3 , As_2Te_3 , As_4Se_4 , Cu_2S , Cu_2Se , Cu_2Te , Cu_4GeS_4 , Cu_2SnS_3 , Cu_2SnSe_3 , GeS_2 , $GeSe_2$, Ge_4Se_9 , Sb_2S_3 , Sb_2Se_3 , Sb_2Te_3 , SnS , $SnSe$, $CdSe$, $CdTe$, $ZnSe$ and $ZnTe$ have been carried out recently (Hasan *et al.*, unpublished) using the methodology outlined in Section 2. Extensive DFT calculations of the electronic structure, interatomic bonding, optical and mechanical properties of a large number of chalcogenide crystals within one method in relation to TBOD enable us to reveal several new findings and hidden correlations on their properties. This could facilitate the exploration and development of new chalcogenide glasses for potential new applications. Table 6 lists the names and structures of these 25 crystals together with some of the calculated properties including the TBOD. In Fig. 12 we plot the distribution of all the BO vs BL pairs in the 25 crystals. No trend or special features can be identified since the composition, structure and bonding in these crystals can be significantly different. However, the TBOD for each of the 25 crystals provides a new perspective. Fig. 13 shows the TBOD of these crystals divided into 8 groups are generally controlled by the first atomic element in the formula (Ag, Cu, As, Ge, Sb, Sn, Cd and Zn) and less on the chalcogen elements (S, Se, Te). It shows that groups lead by Cu or
